SUBJECT INDEX

Compiled by EMMA S. BUSS

Explanation: Numbers in heavy type refer to original articles, parenthetic numbers to abstracts

Abducens paralysis, in herpes zoster ophthalmicus, (333).

Abscess, orbital, (1042).

Abstracts—

1. General methods of diagnosis, (193), (429), (664), (907), (1162), (1448).
2. Therapeutics and operations, (194), (429), (665), (910), (1164), (1449).
3. Physiologic optics, refractions, and color vision, (198), (431), (555), (670), (913), (1165), (1449).
4. Ocular movements, (201), (304), (438), (556), (671), (916), (1169), (1451).
5. Conjunctiva, (202), (304), (441), (559), (672), (780), (918), (1173), (1311), (1453).
6. Cornea and sclera, (203), (306), (443), (560), (673), (782), (921), (1178), (1314), (1455).
7. Uveal tract, sympathetic disease, and aqueous humor, (91), (206), (307), (444), (561), (676), (782), (923), (1181), (1315), (1456).
8. Glaucoma and ocular tension, (91), (207), (309), (446), (562), (677), (782), (923), (1182), (1316), (1457).
9. Crystalline lens, (93), (207), (311), (448), (562), (678), (783), (924), (1036), (1185), (1317), (1459).
10. Retina and vitreous, (94), (208), (312), (454), (563), (679), (784), (925), (1038), (1186), (1317), (1460).
11. Optic nerve and toxic amblyopias, (94), (211), (315), (566), (682), (785), (926), (1189), (1319), (1461).
12. Visual tracts and centers, (94), (212), (317), (457), (568), (683), (786), (1041), (1320).
13. Eyeball and orbit, (96), (213), (319), (457), (569), (684), (787), (926), (1042), (1320), (1463).
14. Eyelids and lacrimal apparatus, (97), (214), (319), (459), (570), (684), (789), (928), (1043), (1322), (1464).
15. Tumors, (97), (321), (460), (571), (789), (930), (1044), (1324), (1465).
16. Injuries, (97), (322), (460), (572), (791), (931), (1045), (1325), (1465).
17. Systemic diseases and parasites, (99), (332), (463), (576), (797), (1052), (1328), (1466).
18. Hygiene, sociology, education, and history, (102), (334), (464), (578), (797), (1053), (1331).
19. Anatomy, embryology, and comparative ophthalmology, (103), (336), (582), (801), (1057).

Accessory nasal sinuses, see Nasal accessory sinuses.

Accommodation, autonomic nervous system in, (1167).

fatigue of, experimental, (670).

Achromatopsia, see Color blindness.

Adaptation, dark, (907).

test of, (210).

evaluation of, (1318).

specifications for, (208).

and vitamin A, (210), (314).

Adenitis, tuberculous, with iridocyclitis, (308).

Adenopapilloma of semilunar fold, (1465).

Adie's syndrome, see Syndrome.

Afterimages, latency of, oxygen deprivation and relation of stimulus intensity and, (434).

Agency Dispensing Policy, rebates and, 84, 660.

Albinism of eyes, complete, (1042).

Albucide, see Sulfanilamide.

Alcaptonuria, ochronosis and, (569).

Alcohol, effect of methyl, on optic nerve and fields, (567).

retrobulbar injection of, (1164).

Allergy, and headache, 77.

hemianopsia from, (1320).

ocular, (1052), (1329).

sensitiveness of mucous membrane, (920).

uveitis, (1315).

Amaurosis, hysterical, traumatic, (786).

of idiocy, infantile, (1460).

inclusion bodies and fate of ganglion cells in, (101).

Amblyopia, constant occlusion in, 289.

in cases of reading failure, 1374.

diplopia with, 1026.

ex anopsia, 740, (1451).

hysterical, (212).

in lens-vitreous changes, congenital, (449).

solar keratoconjunctivitis with, 227.

strabismic, dissociation of form vision and light perception in, 950.

suppression, 469, 1266.

toxic, tobacco and alcohol, (683), 713, 847, (1189).

tryparsamide, (1461).

visual-improvements in, 1024.

and vitamin deficiency, (1319).

and see Abstracts, section eleven.

Amblystoma punctatum, lens induction in, (582).

American Academy of Ophthalmology and Otolaryngology, Section on Ophthalmology, 1944 meeting, 1305.

American Board of Ophthalmology and prevention of blindness, (1331).

American Medical Association, Section on Ophthalmology, 1944 meeting, 775.

American Ophthalmological Society, 1943 transactions, 1033, 1944 meeting, 774.

American Optical Company pseudoisochromatic plates, see Vision.

Anatomy, embryology, and comparative ophthalmology, (103), (336), (582), (801), (1057).

Anatomy of cortical vision, 336.

Explanation: Numbers in heavy type refer to original articles, parenthetic numbers to abstracts

- Anemia cataract with, 1301.
 Anesthesia, evipan sodium, (194).
 local, in ophthalmology, (429).
 retardation of corneal-epithelium regeneration by, (572).
 naphthocaine, 178.
 for operations, (430).
 pentothal sodium, 655, (665).
 procaine, (429).
 tetracaine, (429).
 Aneurysm, arteriovenous, (1040).
 of eyelid, (320).
 of internal carotid, 1299.
 traumatic, (788).
 Angioid streaks of retina, see Retina.
 Angioma of retina, (97), (790).
 Angiospasm, see Retina.
 Aniridia, see Iris.
 Aniseikonia, (1450).
 Anisometropia, vision in, 641.
 Anomalies of the eye, congenital, (678), (782), 1435.
 Anoxia, cataract from, (1036).
 Anterior chamber, cysticercus cellulosae in, (99).
 epithelial ingrowth following cataract extraction, 764, (1182).
 indications for paracentesis of, (783).
 irrigation of, with sulfadiazine, 527.
 Antifreeze, effect of, on eye, (315).
 Antisepsis, preoperative, (666).
 Aphakia, (783).
 retinal-detachment operation in presence of, 288.
 Aqueous humor, fibrin, adhesive power of, 1220.
 reaction of, in diagnosis of ocular neoplasms, (1325).
 Aqueous veins, backflow phenomena in, 1074.
 Arachnoiditis, optico-chiasmatic, 766, 1296.
 Ariboflavinosis, see Vitamin B.
 Arteriosclerosis obliterans, retinitis pigmentosa with, (564).
 Arteritis of temporal vessels, 19, (314).
 Association for Research in Ophthalmology, 1944 meeting, 775.
 papers read before, 933, 941, 950, 1063, 1074, 1206, 1220.
 Asthenopia, from congenital lens-vitreous changes, (449).
 hysterical, (1041).
 treatment of nonpathologic and nonrefractive, 520.
 Astigmatism, biastigmatism, (437).
 determination of axis of 185.
 residual, in ametropias, (913).
 retinoscopy, in, (1167).
 Arteriosclerosis, retinal, (1187).
 Atophanyl therapy in sympathetic ophthalmia, (782).
 Autohemotherapy, subconjunctival, (429).
 Autopsies, eyes from, 529.
 Aviators, black vision and red vision of, (455).
 Avitaminosis, see Vitamins.
 Barraquer technique, see Cataract.
 Behcet's syndrome, see Syndrome.

MASSIVE BILATERAL PRERETINAL TYPE OF HEMORRHAGE
ASSOCIATED WITH SUBARACHNOIDAL
HEMORRHAGE OF BRAIN*

WITH CASE REPORT AND PATHOLOGIC FINDINGS

LESLIE C. DREWS, M.D., AND JEFF MINCKLER, PH.D.

Saint Louis

INTRODUCTION

Both subdural and subarachnoidal hemorrhages of the brain may invade the corresponding cavities of the optic nerve and ordinarily will remain localized in that space, if there is no traumatic rupture of the arachnoid that allows the blood to pass into both spaces. Duke-Elder¹ classifies *subarachnoidal hemorrhage* as: (1) traumatic (the occasional case), due to rupture of meningeal blood vessels usually in a basal fracture, and (2) non-traumatic (the usual case), in which the blood always comes from an intracranial origin; either from (a) aneurysm, usually basal, rupturing into the subarachnoid, (b) spontaneous intracerebral hemorrhage bursting into the subarachnoid, or (c) meningeal hemorrhage in blood dyscrasias.

We shall concern ourselves chiefly with hemorrhage into the nerve sheath from a bleeding basal aneurysm. Most of the reported cases are not associated with hypertension or blood-vessel disease; most are precipitated by some temporary increase of blood pressure; most of these aneurysms are in an artery of the first order and most are in the anterior half of the circle of Willis; occasionally the aneurysm may be located in a cortical

branch. Usually the aneurysm is congenital and often it is associated with supernumerary blood vessels or other minor congenital anomalies of the circle. Occasionally the aneurysm is thought to be acquired as a result of infected emboli, atheroma, or syphilis (Duke-Elder²).

In 1924 Symonds³ reported a series of 124 cases of "Spontaneous subarachnoid hemorrhage" (that is "spontaneous," or nontraumatic). In only 14 of these 124 cases were the fundi described; 3 of these patients had subhyaloid hemorrhages and 6 had papilledema. In this masterful 27-page article the author divides the cases into four clinical groups, patients in the first of which die suddenly, as in other apoplexies, and those in the last of which (a hypothetical group) have such gradual hemorrhage as to be almost asymptomatic until the grand attack occurs. The other groups are a coma- and later-meningeal type, and a purely meningeal type.

Premontory signs and symptoms are often present over many years, and usually are caused by the leakage of varying amounts of blood. Duke-Elder⁴ lists them as: (1) Paroxysmal headaches which are severe, sudden in onset, come on after some exertion, and are often associated

* From the Departments of Ophthalmology and Anatomy, Saint Louis University School of Medicine. Read before the Saint Louis Ophthalmic Society, March 27, 1943.

with tinnitus. (2) Coma, then signs of meningeal irritation with delirium, vomiting, restlessness, severe headaches, neck rigidity, positive Kernig, positive Babinski, and paresis of cranial nerves especially the third and sixth. (3) Ocular signs: The extension of hemorrhage into the optic-nerve sheath produces a fairly characteristic picture of papilledema and hemorrhages, an associated palsy of third and sixth nerves in 70 percent of the cases, and moderate proptosis considered due to the hematoma of the nerve. Almost invariably the ocular signs are bilateral although enough unilateral cases are described to emphasize that this need not be so.

Papilledema is the most common finding. Usually it is slight in amount, and only rarely is it entirely absent. It is almost invariably bilateral, and characteristically comes on with great rapidity (Uhthoff, 1901, described it within 30 minutes of onset). The papilledema is of particular interest because it is supposed to be due to the same essential cause as the papilledema of brain tumor. Many of the reported cases show marked hematoma of the nerve sheath, and not a few cases are reported in which definite constriction of the central retinal vein within the distended subarachnoid space was demonstrated (Dupuy-Dutemps⁵). This obstruction of the central retinal vein within the subarachnoid space as in other papilledemas is supposed to be due to: (1) the increased pressure within the subarachnoid space, (2) the double angulation of the vein produced by the distention of the subarachnoid space; (3) the actual axial elongation of the intra-arachnoid portion of the vein produced by the stretching of the vein between its attachments to pia and arachnoid. In this connection the observation of Dupuy-Dutemps of hemorrhages within the dural sheath due to tearing the

elongated vein where it seems rigidly attached to the dura, is of interest.

The retinal hemorrhages. In the great majority of cases the retinal blood vessels are normal. Usually the hemorrhages are small and located near the disc (Duke-Elder⁶), but in four cases proved with serial sections, MacDonald⁷ found two with large subhyaloid hemorrhages some distance from the disc. Hale White⁸ reported a case with symmetrical, large, brick-red hemorrhages in each eye, about four times the size of the disc and encroaching a little upon it. MacDonald states that *subhyaloid hemorrhages are not necessarily in close contact with the disc*, and that probably the fact that the large retinal arteries usually cross the large retinal veins near the disc may be the factor which in many cases tends to fix the location of the hemorrhages near the disc. According to MacDonald, also, ruptures of the deeper veins would produce punctate hemorrhages, and rupture of the small veins in the fibro-vascular layers would produce striate hemorrhages. All these types of hemorrhages were found in one of MacDonald's cases. MacDonald concludes that *the internal limiting membrane seems to be a definite structure capable of localizing a venous or capillary hemorrhage outside the vitreous body*, and advances this conception as further proof that these hemorrhages are, in fact, not arterial, since arterial hemorrhage frequently ruptures the internal limiting membrane, allowing the blood to penetrate into vitreous. Occasionally the hemorrhages are subretinal, but some of the old authors called preretinal hemorrhages, "subretinal" (see Hale White's article).

Source of intraocular hemorrhage. No continuity between the retinal and nerve-sheath hemorrhage has been demonstrated in any recent cases. Duke-Elder⁹ states that Liebrecht concluded there must be

such continuity, and Hale White had reported the actual continuity. However, Doubler and Marlow¹⁰ also claimed in a case of rupture of an *aneurysm of the internal carotid* with subhyaloid hemorrhage that blood had been forced from the subarachnoid space through nerve substance and lamina cribrosa into the retina, and they had serial sections to substantiate this contention. In such a case the pressure within the subarachnoid might be very high. Paton,¹¹ who pioneered in investigations of the mechanism of papilledema, said that "subhyaloid hemorrhages in subarachnoid brain hemorrhage are the result of direct leakage of blood through the subpial lymph spaces around the lamina cribrosa and through the perivascular lymphatics that surround the central vessels." He believed fully that the subhyaloid hemorrhage directly communicated with the hemorrhage in the subarachnoidal space of the optic nerve. Symonds¹² also concludes that, in his case, blood had been forced through the lamina cribrosa into the subhyaloid space and quotes both Hale White and Doubler and Marlow to show that this may be the source of subhyaloid hemorrhage. In all three of these cases (Doubler and Marlow, Symonds, and White) there was a ruptured aneurysm of the internal carotid artery in which very high pressure might be transmitted to the subarachnoidal space. Because of the question as to the source of hemorrhage, MacDonald investigated his four specimens (in two of which there were large subhyaloid hemorrhages) thoroughly with serial sections and came to the conclusion that blood was not forced from the nerve sheath into the eye. All other reported cases, except those of Doubler and Marlow, Symonds, and White, were conspicuous for the fact that the blood was not forced through the lamina cribrosa.

Riddoch and Goulden¹³ state "The

ophthalmoscopic appearances conform very much with our ideas of venous engorgement of the retina which are seen in its *most marked instance in cases of thrombosis of the central retinal vessel*. The obstruction in hemorrhage of the optic nerve sheath is sudden, thus causing appearances similar to those seen in thrombosis of the central retinal vessel although the *results are not so serious as the obstruction is neither so complete nor so prolonged as in thrombosis*."

Riddoch and Goulden¹⁴ also state that post-mortem evidence indicates that whether or not there will be ocular hemorrhage in cases of subarachnoid hemorrhage depends upon (1) the severity of the hemorrhage, (2) situation of the aneurysm, and (3) presence of scar tissue from previous hemorrhages (arachnoidal adhesions in the cisternae basalis and chiasmatis). Thus if scar tissue prevents the hemorrhage from passing down the optic-nerve sheath, there may be no intraocular signs. If only one optic-nerve sheath is "patent" the intraocular signs, if any, will be present only in that eye.

Diagnosis of hemorrhage into the subarachnoidal space of the optic nerve may be made with considerable certainty when there are papilledema, retinal hemorrhages, palsy of third and sixth nerves, and a history of either head trauma or of a sudden seizure with signs of increased intracranial pressure, or with signs of meningeal irritation. The diagnosis is confirmed by lumbar puncture and the finding of bloody spinal fluid (Duke-Elder¹⁵).

CASE REPORT

Mrs. D. B., white, aged 36 years, a patient of Drs. C. J. Vollmar and R. A. Kinsella, entered St. Mary's Hospital on September 6, 1943, at 10:00 a.m. and died September 30, 1943. At 9:00 a.m. while

preparing for church the patient suddenly complained of severe frontal headaches, and had to be led to a sofa, whereupon within less than five minutes she lapsed into a coma with convulsions in which there were periods of rigidity of extremities, jaws, and back. Her face became fiery red and she vomited profusely. She never regained consciousness. Dr. Vollmar was called and sent the patient to the Hospital within the hour.

Past history. When the patient was 12 years old she and her sister had St. Vitus's dance, from which they both recovered completely within several months. At the age of 14 years, she wandered about for two days without knowing who she was, then suddenly recovered. She had had frequent severe headaches since childhood. Seven years ago the patient had what was diagnosed as meningitis, with stiff neck and vomiting. No lumbar puncture was done. Since that time she had had many more headaches than before. The headaches were very severe frontal headaches associated with increasingly severe nausea and vomiting. She frequently was awakened with severe headaches. She was diagnosed hypertensive $2\frac{1}{2}$ years ago, and one year ago was told not to become pregnant again because of hypertension. She had a fall from a horse 20 years ago without known injury. No other injuries were known to her husband. She had had no operations. There was no definite ocular history, and no history of diplopia.

Family history. Grandfather died of paralysis. Mother died of diabetes. Father and brother both died of coronary disease. One uncle has had a bad heart since youth.

Marital history. One child, nine years of age. Otherwise negative.

Physical examination was made one hour after onset of the present illness. The patient was a well-developed and

-nourished woman of 36 years, comatose, face markedly flushed, breathing rapid and shallow. There was moderate tonic convulsive rigidity. Her jaws were clamped tightly on a gag. The eyes were closed, the pupils moderately dilated and fixed to light and accommodation. Ophthalmoscopic examination by the interne was recorded: "The right fundus shows a choked disc. Left fundus cannot be seen." The blood pressure was 200/104, pulse 98 and regular, respiration 40. Examination of chest showed generalized loud moist rales, which obscured the heart sounds. Babinsky reflex was positive on both sides.

PROGRESS NOTES

September 7th. Patient had purposeful movements of the limbs and occasionally tried to talk. Right Babinsky had decreased and left was negative.

September 8th. The patient's blood pressure was running 100-112/60-80, in both arms. She had severe pain in the right side of the neck posteriorly and winced when this area was touched.

September 9th. She had been moving hands a great deal scratching furiously and beating both hands against abdomen. Her right arm was more active than her left. Blood pressure was now 202/116. Pulse and temperature were normal.

September 11th. Ophthalmoscopic examination recorded by interne: "Numerous hemorrhages are present over the right retinal surface. Left eyeground not visualized." Temperature 102.6°F. respiration 22, pulse 90, blood pressure 182/100.

Spinal tap showed pressure 380 mm. of water. When 7 c.c. of bloody spinal fluid was removed the pressure dropped to 135 mm. of water. General condition remained about the same.

Examination by one of us (L. C. D.):
"The pupils react well to light. The

eyes are turned up and out. Homatropine 1 percent produced dilatation to 8 mm.

"Ophthalmoscopically the entire posterior pole of each eye for a width of about 10 D.D. is covered by a large retinal or preretinal hemorrhage of uniform dark brick-red color through which no fundus details are visible. The hemorrhage seems centered over the area where the disc should be. There is a sudden sharp transition from hemorrhage to the normal retina in the periphery, the edge of the hemorrhage is rather smooth, and the outline is roughly circular as in preretinal hemorrhage. The media are clear. The blood vessels in the visible normal retina are free of arteriosclerosis; the veins are markedly tortuous but only moderately engorged."

Diagnosis: "Massive subarachnoidal hemorrhage of the brain extending down along the optic nerve. It is believed that usually such hemorrhage of the eye is due to compression of the central retinal vein within the subarachnoidal space of the nerve. Very frequently the cause is congenital aneurysm of the basal arteries. Occasionally such aneurysms have been attributed to meningitis of which there is a possible history here."

September 16th. Lumbar puncture: spinal fluid bloody, pressure 85 mm. of water. One cubic centimeter of fluid withdrawn.

September 17th. Ophthalmoscopic examination (L. C. D.), with dilatation ad maximum. "All the gross hemorrhage in each eye has been absorbed. Cannot make out even the location of the discs through a dense grayish haze which seems centered over the disc area to a width of 3 to 4 D.D. The obscured area is much smaller than the hemorrhage first seen on September 11th. The peripheral retina uncovered by the absorbed hemorrhage seems normal."

September 22d. Ophthalmoscopic ex-

amination (L. C. D.) showed no change over September 17th. Lumbar puncture showed the intraspinal fluid pressure to be 235 mm. water. When 10 c.c. of bloody spinal fluid were withdrawn, the pressure dropped to 180; then 8 more c.c. were removed, after which pressure dropped to 85.

September 29th. Ophthalmoscopic examination (L. C. D.). "No change from September 17th and 22d." Twelve hours later the patient had 6 to 8 convulsions; blood pressure was 240-290/110-160. Pupils were dilated but reacted to light, Babinsky reflexes negative. During intervals between convulsions the patient relaxed completely, pupils constricted and were fixed to light. Convulsions continued and *two hours later*, the patient regurgitated a mouthful of fluid, then immediately aspirated it, became cyanotic and respiration became labored and very irregular. Trendelenburg position, oxygen, artificial respiration, coramine, all were ineffective. Respiration gradually ceased, cyanosis increased, and within a minute after respiration ceased, the heart stopped.

POST MORTEM. September 30th, 8:30 a.m.

GENERAL. Rigor mortis four plus. Hypostasis slight. Body is well developed and well nourished. The heart weighs 360 grams, shows no evidence of infarction or scarring. The valve cusps are delicate and competent. The coronary arteries are straight and patent and show minimal atheromatous change. There is grade I (minimal) atherosclerosis of the aortic lining. Microscopically, there is hypertrophy of myocardial fibers, and there are a few lymphocytes in scattered subendocardial foci. The blood-vessel walls are not thickened and there is no evidence of inflammatory reaction. Hyaline change in the walls of the afferent glomerular arteries of the kidney is evident and there is minimal medial hypertrophy of small

arteries. There is marked congestion of the pulmonary vasculature with apparent thickening of interstitial lung tissue. The remaining general findings are minor and irrelevant. Death is considered to be respiratory, incident to the cerebral pathology.

Cerebrospinal system: The brain with membranes exclusive of dura weighs

dissects away with great difficulty. The cisterna cerebellomedullaris is choked with hemorrhage but shows no increase in trabecular consistency. Frank blood is in evidence in a subarachnoid position over the foramina of Luschka. The cisterna superius and the cisterna venae magnae cerebri are similarly engorged. The cisterna pontis shows patches of old

Fig. 1. (Drews and Minckler). Superior view of brain. Note flattening of gyri, absence of free blood in the obliterated subarachnoid space. A, arachnoid granulation.

Fig. 2. Inferior view of brain. Note the large hemorrhage in left frontal pole (H), scattered subarachnoidal blood over the base and stem (S), thickened arachnoid and hemorrhage at the foramina of Luschka (L).

1,370 grams. The gyri are somewhat flattened but there are no basal-pressure markings (figs. 1 and 2). The arachnoidal membrane is thickened diffusely and has a bluish cast. There is no fresh or old subarachnoid blood in evidence over the vertex or sides. The superficial cerebral veins are moderately distended. There is clotted hemorrhage in a subarachnoid position over the medial and inferior aspects of the left frontal lobe. The basal arachnoid is conspicuously thickened and

hemorrhage with marked tenacity of the subarachnoid trabecula. The increase in trabecular consistency in the entire basal cistern (c. interpeduncularis, basalis proper, chiasmatis, and fissurae lateralis cerebri) is marked. This space (fig. 2) dissects with unusual difficulty and incorporates old blood diffusely throughout the trabecular reticulum. This network is interpreted as being not wholly related to the terminal hemorrhage but *incident to previous basal pathology* (arachnitis from

recurring subarachnoid hemorrhage or possibly meningitis—see history).

On the inferior surface of the left frontal lobe there is a gross hemorrhage measuring 2.5 cm. in diameter which dissects into the left cerebrum (fig. 2). Dissection of the basal region reveals the source of the hemorrhage in the circulus arteriosus. There is a gross defect of the anterior communicating artery (fig. 3). The right

Distal to the communicating branch the left artery divides immediately into superior and inferior branches. The anterior communicating artery is disposed in two closely related divisions, an anterior and a posterior bridge. The latter arises as a small branch of the right, and a dilated conical segment of the left anterior cerebral arteries. The anterior bridge has a wide base on both longitudinal vessels

Fig. 3 (Drews and Minckler). Enlargement showing right carotid artery (C), right and left anterior cerebral arteries (ra, la), the aneurysm at the site of the anterior communicating artery (An), the point of rupture of the aneurysm (R), the stellate branching of the left anterior cerebral (br), and the invading frontal hemorrhage (H).

anterior cerebral artery continues past the anterior communicating branch in a normal manner. One small lateral branch is given off at the level of the communicating artery and the distal ramifications are in normal order. The left anterior cerebral artery has a stellate distribution at this level. Laterally, four small vessels are contributed to the brain substance.

and fuses widely in its central part with the posterior bridge. The middle fused part extends in an infundibuliform manner superiorly and to the left, terminating in a rounded bulb with a firm white consistence suggestive of a sclerotic plaque. Inferiorly, the stalk of the aneurysm is in evidence with an aperture communicating with the interior of the artery and

Fig. 4 (Drews and Minckler). Coronal sections of the forebrain and transverse sections of the brainstem showing the disposition of the hemorrhage within the brain. Note the point of entry into the left anterior ventricular horn (a), the obliteration of the septum pellucidum and confluence of the lateral ventricles (b), the continuity through the aqueduct and 4th ventricle (c, d), and through the foramina of Luschka and Magendie (e, f). The dissected arterial circle and removed segment of cerebellum are shown (g, h).

pointing anteriorly and to the left (fig. 3). It is from this aperture that the hemorrhage had its origin, dissecting superiorly into the substance of the left frontal lobe.

Gross coronal sections (fig. 4) reveal the course of the hemorrhage throughout the ventricular system. Entering the

ous seepage of the aneurysm influenced the course of the hemorrhage through brain substance and the intensity of the packing of blood in the ventricular system.

MICROSCOPIC. Sections through the aneurysm show a uniform defective wall with great hypertrophy and absence of an

Fig. 5 (Drews and Minckler). Low-power view of section through floor of ruptured aneurysm (An), the superior infundibular extension of the aneurysm (San), the left anterior cerebral artery (la). Note the defective wall of the aneurysm (Aw).

left anterior ventricular horn the blood perfused the entire system, establishing confluence of the lateral ventricles by destruction of the septum pellucidum, and issuing through the lateral and median apertures of the fourth ventricle to appear in the subarachnoid space of the brain stem and cord. Undoubtedly, the arachnitis in the basal cistern from previ-

elastic membrane (fig. 5, cf. Forbus¹⁶).

Meninges and brain: The arachnoidal membrane is thickened, cellular, and compressed over levels including vertex, lateral surface, base, stem, and cord. Free blood is present except as noted grossly. Meningothelial phagocytic activity is pronounced in the subarachnoid space of the spinal cord, less marked at the levels

of the stem and base. At these levels the trabecular network is dense, with free red blood cells and lymphocytes in the meshwork and relatively few macrophages with pigmented debris. The pia-glial membrane is thick and sclerotic throughout. The intramedullary pathology is not remarkable. There is no evidence of glial,

bulb reveal *free blood in the subarachnoid space in diminishing quantity as the inspection is carried distally*. Close to the chiasm there is free blood with numerous macrophages. Red cells are present in progressively smaller amounts to about the midpoint of the stalk bilaterally (fig. 6). Distal to this point no free cells have

Fig. 6 (Drews and Minckler). Section through the left optic nerve 2 cm. from the chiasm showing free blood in subarachnoid space (Sa). PG, pia glial membrane.

free-cell, or vascular activity suggesting an inflammatory process. Cell changes are nonspecific. The intramedullary small arteries show a minimal medial hypertrophy. Edema is evident but not marked in cerebrum and stem, is absent in the spinal cord and minimal in the optic chiasma. The edema does not extend into the optic nerves. Transverse sections through the latter to within 1 cm. of the

been found but *old hemorrhage is indicated by the presence of scattered macrophages containing pigmented debris*. The arachnoidal space close to the bulb is dilated and shows increased density of trabecula (fig. 7).

Longitudinal sections through one papilla show dilated central vein and moderate lateral shift of the retina. There is a slight forward bulge of the anterior com-

ponent of the lamina cribrosa. Distortion of fibers entering the nerve is not marked (fig. 7). There is an extensive intraretinal hemorrhage (fig. 8). This has dissected into the anterior part of the nerve fiber layer and at all points appears to be separated from the vitreous by a thin,

COMMENTS

When I first saw this case I was struck by the fact that the retinal hemorrhages were far more extensive than any I had ever seen in cases of thrombosis of the central retinal vein, or, for that matter, anywhere else. One might think, as actu-

Fig. 7. (Drews and Minckler). Low-power view of one half the papilla showing lateral shift of retina (R), moderate distortion of nerve fibers entering the optic nerve (N), dilated central retinal vein (V), dilated subarachnoid space (Sa). The anterior fibers of the lamina cribrosa bulge forward slightly. Note absence of blood in an interfascicular position at the level of the lamina cribrosa. The relative position of intraretinal hemorrhage (H) is shown.

but distinct membrane of varying cellularity (fig. 8). Careful search reveals no actual breach in the wall of the retinal vein but the wall is obviously defective adjacent to the hemorrhage with evident diapedesis. The nerve-fiber layer is edematous and the ganglion cells show a vacuolar change with eccentricity and pyknosis of nuclei.

ally stated by Riddoch and Goulden and quoted before, that where the vein is completely blocked, as in thrombosis, we should see the most extensive venous or capillary hemorrhage possible. Komoto¹⁷ described a preretinal hemorrhage 7 by 10 mm. in size (that is about 5 by 7 D.D.) centered over the macula, and not in contact with the disc, in a fatal case of pur-

pura. I have not been able to find any case in the literature where the retinal hemorrhage was as extensive as in the case here described. Of course, I suppose where hemorrhage is as extensive as in this case it is unusual to find it limited to the retina; in most cases, undoubtedly, it

the hyaloid, forcing its way into the vitreous, even if the blood does travel over the perivascular spaces. If such a hemorrhage, coming through the disc, is to be localized as a preretinal hemorrhage it must be that it is easier to extravasate beneath the internal limiting membrane than

Fig. 8 (Drews and Minckler). High-power view showing retina (R), edematous nerve-fiber layer (N), intraretinal hemorrhage (H), separated from the vitreous by a cellular membrane (M). A retinal vein with a defective wall adjacent to the hemorrhage is shown (V).

bursts into the vitreous, making ophthalmoscopic examination impossible.

It seemed to me that if blood ever were forced through the lamina cribrosa into the eye, this would be a case where such a finding could be expected. In this connection one might wonder why a pressure sufficient to force blood into the eye through the nerve substance and lamina cribrosa would not immediately rupture

to break it and the hyaloid. Moreover, if the blood came through the disc one might expect to find some blood in the canal of Cloquet.

The hemorrhages were described in the first examination as "retinal or preretinal." It was thought that even if they were preretinal the gravitational effect diagnostic of preretinal hemorrhages would be absent because of the patient's

prone position. The smooth outline between hemorrhage and normal retina also suggested preretinal hemorrhage. There is considerable confusion between the terms preretinal and subhyaloid. I have used them interchangeably. In this case, which had some of the characteristics of preretinal or subhyaloid hemorrhage, the hemorrhage actually seems to be entirely *beneath the internal limiting membrane*, which is intact but separated from the nerve-fiber layer by some old hemorrhage and detritus. Some authors have reported that preretinal hemorrhages actually lie beneath the internal limiting membrane; others have found the preretinal hemorrhage located between the internal limiting membrane and the condensation membrane of the vitreous. Duke-Elder¹⁸ says that "usually the blood is poured out beneath the internal limiting membrane which it finds little difficulty in stripping off and raising up so that it forms a film immediately *overlying the retina*; sometimes, however, the internal limiting membrane may be ruptured in which case the hemorrhage forms a similar film between it and the vitreous; and occasionally blood bursts through the face of the vitreous and forms a diffuse opacification in the gel." If the internal limiting membrane is actually formed by the expanded ends of the sustentacular cells of Müller it seems strange that it could easily be detached. Unfortunately only the posterior half of the one eye was removed; therefore, the eye specimen is not all that could be desired. Both optic nerves and the chiasma, however, were removed.

From a clinical standpoint it seems certain that since all the gross *retinal* hemorrhage which had been so extensive was resorbed in only six days or less, the blood was situated in a location having very good circulation. It has often been re-

marked that a large preretinal hemorrhage may be absorbed (and unfortunately recur) with surprising rapidity, but if the hemorrhage actually were situated between the internal limiting membrane and the vitreous, one would not think it likely that it could be rapidly absorbed. Unless there were multiple large tears through the internal limiting membrane it is difficult to believe that there could be a rapid absorption of a truly preretinal hemorrhage. However that may be, it seems certain that, theoretically at least, a large hemorrhage entirely beneath the internal limiting membrane could be rapidly absorbed, whereas a similar hemorrhage between the internal limiting membrane and the vitreous probably could not. In the possible rapidity of absorption, therefore, we may have a suggestion as to the exact situation of a hemorrhage, which appears to be "preretinal."

It seems unfortunate to call hemorrhages beneath the internal limiting membrane either "preretinal" or "subhyaloid" since the hemorrhage really is intraretinal. An intraretinal hemorrhage should be expected to give rise to more retinal damage than a truly subhyaloid one, therefore there is clinical value to differentiation between the two types of "preretinal" hemorrhages. However there seems to be no way in which the two types of hemorrhages can be distinguished ophthalmoscopically, so the use of one term for both conditions seems advisable.

At the autopsy I was rather chagrined to find no gross hematoma of the optic-nerve sheath. Microscopically, we found no hemorrhage in the sheath; there was a small amount of blood in the sheath near the chiasm. This raised the question whether or not there ever was any subarachnoid hematoma of the nerve. All we can say is that we did find moderate hydrops and considerable detritus in the

subarachnoidal space of the nerve, *which was due to hemorrhage* (see pathology report). When one recalls that the very large preretinal hemorrhage was all absorbed, so far as could be observed with the ophthalmoscope, within 6 days, it seems quite certain that even an extensive subarachnoidal hemorrhage into the nerve sheath could have been absorbed within 24 days, the period of time between the onset and the fatal attack.

If the first subarachnoidal brain hemorrhage produced a hematoma of the nerve, why did the fatal attack 24 days later fail to do so? There may have been minor attacks in between the first and fatal attacks as well, as indicated in the history. Perhaps the fatal hemorrhage did not have time to penetrate into the optic-nerve sheath; but probably what happened was that the extensive adhesions in the cisterna basalis and chiasmatis caused by the first hemorrhage prevented the fatal hemorrhage (and any others which may have intervened) from reaching the optic-nerve sheath.

In some personal discussions, there has been disagreement that a large preretinal hemorrhage in each eye associated with subarachnoidal hemorrhage of the brain justified the diagnosis of subarachnoidal hemorrhage of the optic nerve. However, I believe that the literature substantiates the validity of my conclusion that large preretinal hemorrhages in each eye in a patient not the victim of general vascular disease, associated with the typical spinal-fluid findings in subarachnoidal hemorrhage, do justify the diagnosis of subarachnoidal optic-nerve hematoma, even though in this case the actual hematoma was not found to be present 24 days after the onset. None of the reported cases in the literature failed to show such a hematoma; but also none of the reported cases had the time intervals reported here.

The specimen shows slight but definite papilledema; whether this was present beneath the "preretinal" hemorrhage when first noted no one could possibly say. I have no clinical doubt that it was. No one could possibly deny, however, that the papilledema could have been produced by the supposed later hemorrhage with increased intracranial pressure, or even by the fatal hemorrhage.

The autopsy revealed only minimal arteriosclerosis, yet the patient had been diagnosed hypertensive by two competent practitioners. It is an interesting question to ask whether she had periods of acute hypertension related to minor attacks of bleeding from the aneurysm, similar to the acute hypertensive attacks she had while in the Hospital. The sclerosis of the renal arterioles seemed sufficient to account for a hypertension.

The crux of the problem of massive preretinal hemorrhage associated with hematoma of the optic-nerve sheath in subarachnoidal hemorrhage is that such massive hemorrhage is so unusual in papilledema associated with brain tumor. What is there about subarachnoidal hemorrhage which favors preretinal hemorrhage? Certainly we would not think that the pressure in the subarachnoidal space would be so very different in the two conditions, and even if it were very different it would still not account for hemorrhages more extensive than those usually seen in actual thrombosis. Of course, in speed of development the two conditions may differ. The more one ponders this the more sympathy one has for Liebrecht, Doubler and Marlow, Symonds, White, and Paton's opinions, which apparently we must discard, that the retinal hemorrhage comes directly from the nerve-sheath hemorrhage. The fact that the pre-retinal hemorrhage may not be in contact with the disc at any time of its development as well as the absence of his-

tologic proof, makes this opinion seem untenable.

CONCLUSIONS

1. A case of very extensive bilateral preretinal hemorrhage, associated with subarachnoidal hemorrhage from a congenital aneurysm of the communicating branch of the anterior cerebral artery, is reported. When examined pathologically, 24 days after the onset of the brain hemorrhage, only the remains of hematoma were found in the subarachnoidal space of the optic nerves. It is concluded that hematoma had been present but was absorbed.

2. It is suggested that if a "preretinal" hemorrhage absorbs very rapidly the hemorrhage probably is situated beneath the internal limiting membrane where the cir-

culatation may be excellent. Such a hemorrhage really should be considered intraretinal, since the internal limiting membrane is considered a part of the retina.

3. After one or more subarachnoidal hemorrhages, adhesions may form in the cisterna basalis on one or both sides; a later hemorrhage may then fail to produce ophthalmoscopic signs in one or both eyes.

4. As far as I can find this case presents the largest preretinal type of hemorrhage described in the literature (about 10 disc diameters, each eye). There was no evidence that blood had been forced from the supposed hematoma of the nerve sheath through the lamina cribrosa.

5. Why do massive preretinal hemorrhages occur in subarachnoidal hematoma of the optic-nerve sheath frequently, and rarely in ordinary papilledema?

EPIDEMIC KERATOCONJUNCTIVITIS FROM A SUBJECTIVE VIEWPOINT*

THOMAS D. ALLEN, M.D.

Chicago

The present epidemic of keratoconjunctivitis, although slightly different from certain epidemics described under the heading "Superficial punctate keratitis," should, in my opinion, be considered in the same category. The Editor of the *American Journal of Ophthalmology* (1943, v. 26, Feb., p. 199) agrees with this opinion. I have read many of the articles on both subjects. In several of them reference is made to the fact that clinical assistants became infected, but nowhere could I find that a physician had written of the disorder from the subjective standpoint. For this reason it has seemed important to bring before you a slightly different angle of the problem than the purely objective one, which has been adequately presented in numerous recent papers. Also, it has seemed to me expedient to personalize the danger to physicians, and especially ophthalmologists, of infecting their own eyes. One of our Chicago ophthalmologists fell prey to the disease last summer, but very few others knew about it until after I contracted it early in January. Since my illness I have tried to spread the gospel of meticulous cleanliness from Chicago to Mexico City.

The objective signs need not be reviewed here in detail; briefly they are a gradually increasing conjunctival hyperemia and folliculosis, moderate to severe conjunctival edema, some sticky secretion, no pus, occasional pseudo-membrane, slight photophobia, considerable edema of the lids, and regional adenopathy; later often superficial corneal spots varying greatly in size, density, and numbers;

seldom iritis. There is a gradual return to normal, as a rule in three to six weeks, except that the corneal spots linger and usually interfere with visual acuity for several months.

Subjectively, I have had a peculiar mixture of the scientific attitude of the practicing physician with the irritation of the restless patient, which is certainly not scientific. I found myself making my own diagnosis (a most dangerous procedure) and wanting all the corroboration I could get. I did what physicians universally deplore and discountenance; that is, I consulted many physicians and compared their diagnoses and recommendations.

I had seen, December 24 and 28, 1942, a patient (E. P. E.—D1369) with a most peculiar conjunctivitis. He had been in the hospital under the care of a very competent ophthalmologist for about a week, but his doctor had been called out of town and he came to me. In addition to the conjunctivitis, which was moderately severe but without much edema, he had a definite aqueous beam, seen with the slit-lamp, and some fine precipitates on Descemet's membrane. I looked carefully at the cornea with the slitlamp, and I believe I would have seen any superficial corneal spots if they had been present. On January 12, 1943, after he had seen several other ophthalmologists, he went to Dr. H. Gradle's office, and by that time he had developed the corneal opacities characteristic of the disorder.

About January 10th (Sunday)—that is, 13 days after I last saw E. P. E.—I noticed a slight watering of my own right eye, and the following day a stickiness of the eyelids. I have such sensations one or twice a year, and I have found

* Presented before the American Ophthalmological Society, at Hot Springs, Virginia, June, 1943.

a single application of 1-percent silver nitrate usually suffices to restore the tissues to normal in 24 hours. This time, however, the situation did not improve but was even worse on January 12th (Tuesday) at which time, by coincidence, I attended a luncheon at which the subject of this epidemic was discussed. That evening I went to a nearby ophthalmologist, who made a smear and a culture; the clinical appearance was that of an ordinary conjunctivitis but without much discharge; the laboratory report was "no organisms found."

The next day, January 13th, the eye was distinctly worse. I called Dr. Peter Kronfeld, who admitted it might be the epidemic form, and we decided I should go to the hospital to minimize the danger of contagion at home, and so that studies could be more conveniently conducted. The laboratory report of scrapings of the conjunctiva was: "few staphylococci; few larger structures which look like staphylococcal cells; a number of eosinophiles." On the following day a more critical study was made of another smear; several observers noted "a preponderance of monocytes." About January 14th (Thursday) the eyelids began to be heavy, especially the upper one, and the following day subconjunctival hyperemia was marked and the right preauricular gland was palpable.

One-percent, later 0.25-percent, formaldehyde ointment was used in the left eye to prevent, if possible, its involvement; and in the right eye to see if it would have any effect. It was not, however, used consistently because of the discomfort it caused. I dropped 5-percent sulfathiazol solution into each eye six or seven times a day for the first week; also aqueous mercurochrome 1-percent several times a day for three days, 13th, 14th, 15th. Warm boric-acid compresses were used at first, but cold compresses seemed much more comfortable. Foreign-protein therapy was received as follows: (a) Pro-

teolac 5 c.c. intramuscularly, January 14th and 15th; (b) 50,000,000 triple typhoid vaccine intravenously, January 16th—it produced a chill and fever (temp. 101.6°F.) and what the colored folk call "a misery" for 36 hours.

I made it a point to have a paper handkerchief for the right eye on the right side of the bed or chair, and one for the left eye on the left side; two towels also and two handkerchiefs; but I caught myself wiping the left eye with the same towel and handkerchief I had used for the right eye, and this not just once but several times! It was most difficult to develop suddenly an entirely new technique for cleaning my face!

About January 18th the left eye began to tear and the next day a slight sticky secretion was present. Within a day or two the left preauricular gland became tender. It was hard to say just when it became tender; I felt for it many times every day; the onset of tenderness was almost imperceptible.

On the 23d of January minute subepithelial corneal spots were found in the right eye by Drs. Harry Gradle, Sanford Gifford, and others. Up to this time the visual acuity had not been affected. On January 18th Dr. Kronfeld had sent a request to Dr. Sanders at the Presbyterian Hospital, New York City, for some convalescent serum. This was not immediately available; it seemed much longer than the four days it was before it arrived on January 22d. On that day I was given 50 c.c. intravenously; the dose was repeated the next day, and that evening I started to Texas, as it was quite evident I would be out of circulation, as far as my practice was concerned, for another month. On the train I found it difficult to read, and my morale was pretty low when, between trains at Saint Louis, I called on Dr. Hayward Post. The following day newsprint and the menu could be read only with the help of a

+13.00D. magnifier. Tobacco smoke was unbearable, so I had to stop smoking and keep away from others who smoked.

Two days later, January 27th, I arrived in Houston and immediately saw Dr. Everett Goar. He found my visual acuity varied between 18/200 and 20/100; it was not constant and it was about equal in the two eyes. There were still some preauricular tenderness and moderately severe hyperemia of the eyes, but the edema was less. Dr. Goar started me on vitamin C intravenously (cenolate, an Abbott preparation of ascorbic acid), 200 mg. daily. At that time it was very difficult to read, even with a magnifier, and I had to approach to within 10 to 12 feet of a street sign to read it. Even the spots on playing cards were not distinguishable beyond 12 inches. All lights were multitudinous and extraordinarily dazzling and confusing. Neither a single nor a multiple pinhole disc was of any avail in reducing the discomfort from the lights, although dark glasses were helpful. But even with this poor vision I had no difficulty in crossing streets or on uneven pavements.

After the first two treatments it seemed my visual acuity improved, and I thought I could notice the difference within an hour after a treatment. After the fifth treatment the vision was about 20/70, occasionally even better, and I began to wonder if I could get some pleasure out of the experience—possibly a trip to Mexico City even!—that is, my morale rose. But from the time I left Houston the progress was so slow and so often there would seem to be a regression (fresh spots?) that I became very much discouraged and arranged for immediate return to the States in spite of the fact that Dr. Silva reassured me that all would soon be well. Dr. Ramon Castroviejo saw me just as I was leaving Mexico City and did his best also to cheer me up.

Even back in Houston, February 6th to 12th, the improvement was slow.

Acuity varied between 20/40 and 20/30+. It seemed to vary from hour to hour. I attended a clinic with Dr. Edward Griffey and had to admit I did not see details clearly enough to hazard a diagnosis. However, in the dark room I found, with the electric ophthalmoscope, that my acuity was almost normal. Again my morale picked up and as there had been no secretion of any kind for 10 days I left for home, determined to do my best whatever happened.

During the last few days in Houston I had started dionin 5 percent in each eye daily. This I continued for nearly a week. Then all treatment was stopped. I had had 200 mg. cenolate (ascorbic acid) intravenously daily for 17 days. When I arrived in Chicago, February 14th, the acuity was 20/30± and 20/20±, R and L, respectively, with my correction, and this could not be improved by any change in the glasses. The lights were still multitudinous, each one being surrounded by many others, but the halo was not so glary and the single center light or object was more clearly defined. Those who examined my eyes with the slitlamp said they saw that the spots were thinning out—that is, each one was less dense. The progress has continued and now after 10½ weeks, I no longer have halos, my vision with correction is 20/20+ with each eye; the "spots" can still be seen by any keen observer in each of my corneas. I think I can say I have recovered my mental and emotional equilibrium. I can never forget, however, how angry and disgusted I was with myself for the careless moment when, after examining my patient and before washing my hands, I must have fingered my own eyelids.

Entirely from the subjective standpoint I would say cold boric-acid compresses, intravenous vitamin C, and encouragement were the factors I found to be most helpful.

122 South Michigan Avenue.

TEMPORAL ARTERITIS*

CASE REPORT WITH EYE FINDINGS

LAWRENCE T. POST, M.D., AND T. E. SANDERS, M.D.

Saint Louis

Arteritis of the temporal vessels was originally described by Horton, Magath, and Brown¹ of the Mayo Clinic, in 1934. They reported two cases and concluded that this form of a localized arteritis was a previously undescribed entity. The next case of this condition was reported by MacDonald and Moser,² in 1937, the further history of whose case is described by the present authors. Three months after the report of this case, Horton and Magath³ reported a total of nine cases in the literature, seven of them being their own. These cases were so similar, both clinically and pathologically, that they again concluded that this was a new disease entity. This contention has been accepted by most authors, the number of cases now in the literature being approximately 26.⁴⁻¹⁴ With few exceptions these cases have been reported in this country, but three were seen in England,⁴⁻⁵ and one each in Uruguay,³ France,⁶ and Canada.⁹

The disease seems to be limited to elderly persons, the youngest reported being 55 years old. The onset is characterized by headache, which is more or less constant and which tends to be more severe at night, general malaise, weakness, fever, anorexia, and loss of weight. From two to five weeks after onset the temporal arteries become very prominent and tortuous, with inflamed raised nodules along their course. They are very painful and tender to the touch, this condition being present to a lesser extent over the whole scalp. In the early stages pulsations are

present, but these disappear as the condition progresses. The temperature usually ranges from 98°-103°F., and the white-blood-cell count from 7,500 to 13,500, with a reduction in the red-blood-cell count to around 3,500,000. Usually there are no other significant physical findings.

The disease generally runs a chronic course of four to six months' duration, the patient being often bedfast for long periods, but never dangerously ill. Pain in the head is usually the most marked complaint. Complete recovery has occurred in every case on record. There is no specific treatment. However, the symptoms in most cases are completely relieved by removal of portions of the temporal artery for biopsy.

The pathologic picture is characteristic and serves to differentiate this condition from periarteritis nodosa and rheumatic arteritis. Pathologically the lesion is a chronic periarteritis and arteritis. There is an infiltration of round cells in the adventitia around the vasa vasorum and in the media of the larger vessels. This infiltration is present to such a marked degree in some areas of the media that complete necrosis with hemorrhage is present. In the areas of destruction of the media it is replaced by a granulomatous type of lesion in which many giant cells are invariably present. The intima in most places is much thickened. This reaction usually reduces the lumen to a marked extent, which in many areas is completely occluded by thrombi. The gross nodular areas represent the cellular infiltration around the vasa vasorum. The etiology is unknown, but the inflammatory appearance of the lesions suggests a low-grade infection. The advanced age suggests that

* From the Department of Ophthalmology, Washington University, and the Oscar Johnson Institute. Read at the seventy-ninth annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June 10-12, 1943.

degenerative changes in the arterial walls may be a factor.

The following report of a case of temporal arteritis does not represent an addition to the total number in the literature, as this case is the third to be reported, having been described previously by MacDonald and Moser² in 1937.

REPORT OF CASE

The patient, a white housewife, aged 66 years, was examined by Dr. L. D.

Fig. 1 (MacDonald and Moser). Low-power cross section of temporal artery, showing inflammatory reaction in the media and a marked proliferation of the intima ($\times 20$).

Thompson of Saint Louis on July 8, 1941, because of failing memory and mental deterioration.

Past history (an abstract of the case as reported in detail by MacDonald and Moser²). The patient entered a hospital in Indianapolis on March 1, 1935, because of pain in the temples, fever, sweats, and general malaise. About four weeks before she had noted a tender area in front of the right ear. About a week later the left side of the face became swollen

and tender. At this time she became aware that the temporal arteries were prominent, red, and tender. General malaise and weakness were pronounced, and fever and sweats were present every night. Her past history was of no importance in this connection.

Physical examination at this time revealed the left temporal artery to be very prominent from a point just above the tempero-mandibular joint for a distance of about $2\frac{1}{2}$ inches. It was thickened, tortuous, the caliber irregular, and the surrounding tissue hyperemic. Pulsation was present throughout the course of the vessels at the time of the first examination, although this became very much diminished a little later. The right temporal artery was less acutely involved, but pulsation was definitely diminished. The preauricular and postauricular glands were enlarged and tender. Two teeth were found to have periapical abscesses. Both optic-nerve heads appeared normal, and the retinal vessels showed about the usual change for her age. The heart was not enlarged. The blood pressure was 148/90. There was a definite pulsation felt in the supra-sternal notch. The remainder of the examination was essentially normal.

Except for a slight anemia, the blood examination and serology were normal. Later urinalysis was normal, although a faint trace of albumin and a few casts were noted shortly after admission. X-ray studies of the chest showed the heart to be of normal size.

On March 29th a section of the right temporal artery (three centimeters) was removed for histologic examination. This showed marked hypertrophy of the intima, almost occluding the lumen, with a scarcity of nuclear elements and tendency

to hyalinization (fig. 1). The media showed almost total destruction and replacement by inflammatory cells of fibroblastic variety. Upon the external border of the media in certain zones were huge multinuclear giant cells. (fig. 2). The adventitia was atrophic. Following the removal of this segment, the temperature became normal and remained so until the patient left the hospital one week later. The patient reentered the hospital on May 13th. She had gained much strength and her general appearance was much improved. She had no fever after the first week. The incision over the right temporal artery was healed. The left temporal artery was smaller and showed no pulsation. It still showed some evidence of inflammation. The eyegrounds were normal. The remaining physical findings and the laboratory examinations were as at first admission. After dental extraction, the patient was discharged.

She was again seen on August 6, 1935, at which time she stated she felt well in every way. The blood pressure was 160/110. The left temporal artery appeared normal, and a normal pulsation was present. At this time there appeared to be an increased narrowing of the temporal vessels and more pulsation in the suprasternal notch. Examination in June, 1936, showed essentially the same findings as the year before.

Interval history. The patient had remained entirely well until two years ago when some mental deterioration was first noted. This had been characterized by memory defect, periods of aphasia, some intermittent depression, and general slowing of mental activity. There had been some tendency to slow progression.

Physical examination (July 8, 1941). The patient was perfectly oriented and rational, but reacted quite slowly. There was a smoothness and lack of wrinkles in the

face suggestive of Parkinsonism, but there was no tremor. There were one or two devitalized teeth. The tonsils were barely visible, the remainder of the pharynx being normal. There was some scarring in either temple, but no inflammatory reaction was present. The thyroid gland was not unusual. The right carotid

Fig. 2 (MacDonald and Moser). High power through wall of temporal artery, showing chronic granulomatous inflammation in media ($\times 150$).

was definitely dilated. A pulsating mass could be felt extending 2 cm. above the right clavicle, probably an aneurysm of the innominate artery. This was confirmed by fluoroscopic examination, which showed a definite widening of the base of the heart with a pulsating area extending from the right border of the arch into the neck. Over the aneurysm the second heart sound could be heard clearly. Blood pressure was 182/104 in the right arm and 186/112 in the left. There was widening of the heart at the base, particularly toward the right. Sounds, rate, and rhythm were normal except for an accentuation of the second aortic sound. The lungs showed a moderate amount of

emphysema, but were otherwise normal. The examination of the abdomen, pelvis, and extremities revealed nothing unusual.

Laboratory examination. Red-blood-cell count was 4,220,000 and the white-cell-count 7,600. Differential blood count showed segmented forms 54 percent, stab

Fig. 3 (Post and Sanders). Fundus drawing, right eye.

forms 5 percent, lymphocytes 38 percent, and eosinophils, monocytes, and basophils 1 percent each. The fasting blood sugar was 76 mg. percent. The Kahn test was negative. The basal metabolic rate was -14 percent. The urine was acid with a specific gravity of 1.010, and was negative for albumin and sugar. The microscopic examination showed only an occasional white blood cell. X-ray examination of the skull showed a questionable erosion of the floor of the dorsum sellae, and that of the chest a cardiac enlargement with a definite widening of the supracardiac shadow.

The patient was also examined by Dr. A. B. Jones, a neurologist, who reported that the patient was merely an "old woman," older than her years, with no localized findings. He thought the findings were due to cerebral arteriosclerosis.

Ophthalmoscopic examination was done July 9, 1941, by one of us (L.T.P.). The patient had no ocular complaints. The vision was normal, glasses being worn for close work only. The patient's husband was in the hospital because of detached retina, and the ophthalmoscopic examination was done as a matter of interest in view of the past history, and not at the request of the patient, who did not desire an eye examination since she had no eye symptoms. On being informed that the eyegrounds were unusual, she consented to having photographs made of them. The media were clear. The discs were of good color and outline. The arteries showed a marked sclerosis with irregularity of caliber and thickening of the walls approaching the copper-wire stage. In the right eye along the course of the superior temporal artery above the macula were two areas of apparent sheathing, the larger being about one disc diameter in length, the smaller, one half its length, being near the disc. Other similar lesions were noted in the peripheral branches of this artery, and another small area in the superior nasal artery adjacent to the disc. In these places the arterial wall seemed to have undergone a fusiform thickening which was deep red in color. The reflex over these areas was markedly impaired, and the blood column could not be seen. The surrounding tissues showed no reaction nor scarring. Below and nasal to the macula were three confluent areas of silvery exudate. They had indefinite borders, the whole area being about the size of the disc. There was no inflammatory reaction present. No hemorrhages were noted (fig. 3). The left fundus was not unusual except for the sclerosis of the vessels.

On March 28, 1942, it was found that the general condition was somewhat improved on general supportive treatment. She was complaining of some inability to

control the flow of urine. Dr. D. K. Rose found a hyperplastic urethritis which was treated by fulguration in Barnes Hospital on April 3, 1942. At this time the general laboratory findings were essentially as noted previously. The appearance of the fundus of the right eye was essentially unchanged.

The patient died very suddenly of a cerebral hemorrhage on September 12, 1942.

COMMENT

Although many of the cases of temporal arteritis described in the literature have definite eye findings, very little attention was given this phase of the condition until several months ago, when Johnson, Harley, and Horton¹⁴ reported three cases in which there was marked loss of vision. In their first case a quadrant field defect was present in one eye with nothing in the fundus except a few ischemic areas to account for the loss. In the other eye the vision was reduced to light perception only, with occlusion of some of the upper branches of the central retinal artery and ischemic elevation of the upper margin of the disc. In the second case the vision of the right eye was limited by a corneal leucoma to perception of hand movements. The fundus of this eye was not unusual except for mild arteriosclerosis. In the other eye the vision was completely gone. The optic disc was mildly edematous and slightly pale. From the temporal margin an irregular, whitish, slightly raised region of exudation extended outward about one disc diameter. Several small hemorrhagic extravasations were present along the superior nasal vessels and above the disc. Several days later there was a sudden, complete loss of vision in the right eye, with no apparent local cause. The patient in the third case had no vision in the right eye and 3/30 in the left. The fundus of the right eye revealed a

rather pale disc, mildly edematous, with an area of localized edema of the retina between the disc and macula in which there was a slightly reddened area suggestive of a cherry-red spot. The optic disc of the left eye showed one diopter of edema and the lower temporal quadrant appeared rather pale. The veins were engorged. The authors concluded that in these cases the mode of onset of loss of vision suggested occlusion of the arterial blood supply of the retina or optic nerve. The evidence of occlusion in the retina was insufficient to explain the complete loss of vision, so this must have occurred in vessels too far back to produce fundus lesions.

In the other cases reported, the eye findings are mentioned only incidentally and in relatively little detail. Even so, approximately one third of the cases in the literature show some significant eye lesion. In the series of seven cases reported by Horton and Magath,³ two cases presented "evidence of phlebitis of one of the retinal veins with hemorrhages and exudates" and one patient had diplopia. In one of the cases reported by Jennings,⁴ the left eye was completely blind on admission, having suffered a gradual loss of vision for one week. The disc was pale, with small central hemorrhages, and the retinal arteries were narrow. The right eye was normal at this time, but within six days a similar picture developed in this eye with complete loss of vision. The diagnosis of the eye consultant was bilateral obstruction of the retinal arteries. Bain⁵ stated that in his case there were severe photophobia and bilateral "peripapillary atrophy." Both of the cases reported by Dick and Freeman⁷ presented blurred vision. In their first case, the vision of the right eye had been poor since birth. During the course of the disease "the vision in the left eye became blurred. The optic disc was twice the normal size

and was slightly edematous. A small hemorrhage was present on the disc. The visual field was reduced to a small point." There was no statement as to the final visual result. Their second patient complained of soreness of the eyes and blurred vision with diplopia for one week. Examination showed "tortuous retinal arteries, sluggish extraocular movements, and poor vision in the right eye." In the case reported by Scott and Maxwell,¹⁰ the fundi were normal at the onset. The patient was also found to have a diabetes with a high renal threshold. About two months later she was complaining of loss of vision in each eye, more in the right. The fundus of this eye could not be seen because of opacity in the lens, whereas the left showed no change in the arteries, but numerous small patches of exudate were seen in the peripapillary area.

In the experience of both authors of this report the fundus picture in this patient seemed unique. To our knowledge no similar arterial lesion has been previously described either in temporal arteritis or in any other vascular condition. The nearest picture approaching the appearance of this fundus was seen in plate 56 in the Wilmer Atlas. The plate is entitled "retinal arteriosclerosis," but from the description there had been a marked loss of vision apparently from an occlusion of the arterial blood supply occurring at the time of a cerebral hemorrhage. In another plate of the same eye (no. 26), made three months later, the localized arterial lesions had disappeared, but a marked generalized attenuation of the retinal vessels was present with glaucoma.

The exact nature of the localized arterial lesion seen in our patient presents a problem in interpretation. It does not seem to be an area of acute inflammatory arteritis related directly to the lesion in the temporal artery, as it did not take place for some months after the temporal

lesion occurred. Also there was no evidence of periarteritis or reaction in the surrounding tissues, as would have been expected in the case of an acute inflammatory lesion, the changes here being localized in the wall of the artery. From the appearance of the fundus alone, the best conclusion is that arterial changes are on a degenerative basis, but this does not explain the brilliant-red color of the localized areas. Whether inflammatory or degenerative, the lesion at this stage must have been relatively inactive as the appearance of the arteries was unchanged after eight months. The area of exudate could be an infarct caused by an occlusion of a small branch of a retinal artery. It is obvious that the arterial degenerative changes are not restricted to the retina, for the patient had an aneurysm of the innominate artery and had marked cerebral sclerosis, dying of a cerebral hemorrhage. It is possible that the whole fundus picture could be explained on the basis of the patient's arteriosclerosis and hypertension, although the appearance of the local lesions is unique.

Despite the fact that eye lesions are very commonly seen accompanying temporal arteritis, we believe that no particular one is characteristic. The two commonly seen are occlusions of the central retinal artery or larger arteries, and a localized arterial lesion with hemorrhages or exudates not unlike those seen in certain cases of arteriosclerosis. It is also possible that certain fundus changes diagnosed as arteriosclerotic might be degenerative similar to those seen in this patient.

We also agree with the statement made by many other authors that the arterial disease is not confined to the temporal and ophthalmic vessels, but is scattered extensively throughout the vessels of the body, especially those of the head and neck. We are inclined to believe that the

condition is fundamentally a degenerative one, which at times undergoes a localized acute inflammatory phase, this being particularly prone to occur in the temporal

vessels. The fundus picture in our case may represent one stage of inflammation in a retinal artery.

MILITARY OPHTHALMOLOGY*

WILLIAM THORNWALL DAVIS, M.D.

Washington, D.C.

In the Military Surgical Manual of the National Research Council for Ophthalmology and Otolaryngology,¹ the Surgeons General of the Army and of the Navy set forth a fact that is not yet fully grasped by the profession at large. They have not strongly emphasized the fact that the overspecialization which has taken place since the last war cannot be carried over into the military and naval services. They have, through the medical departments of the Army and of the Navy, placed the ophthalmologists in their special work to a remarkable degree. Speaking as a veteran of two major and several minor wars and having no inhibitions and no reason to tone down the hard necessities, I must tell you that the services need doctors, great numbers of them. When a major engagement takes place, all the doctors in the world would not be sufficient.

The need for experienced specialists is largely confined to base hospitals and hospitals in the home country, also to the large Army Posts and Cantonments. It is clear, therefore, that, compared to the total number of doctors in the service, there is need for relatively few ophthalmologists. It must be obvious also, that many ophthalmologists will have, of necessity, to become Army surgeons, in any field, no matter how far removed from their specialty. Our specialization has become too narrow. The use of ophthalmologists for purposes other than ophthalmology is not purposely done by the Army and Navy. It is a military necessity.

The stern necessity of war has reduced the previous physical standards includ-

ing those for eyes. Before the attack on Pearl Harbor by the enemy, our standards were those of peace time, when physical perfection was more or less required. We had a great population from which to draw and a pitifully small Army that had been neglected and starved of necessities in the matter of modern equipment. There was, as has ever been in our history, a neglect of preparation for the inevitable. The result now, as always, is terrific waste of lives and material and money. The hurried building of enormous fighting forces on land and sea necessarily results in confusion and waste in time, effort, and the lives of our sons and resources. The pacifists, the "sob sisters," the spirit of "I did not raise my boy to be a soldier," some of the educational institutions that exercised very considerable antimilitary and antipreparation-for-war influence, have done us irreparable injury, not to speak of the lesser influences such as birth control and alien peoples among us who have quietly, skillfully, and continuously undermined our morale; all enemies of the Republic, dangerous and destructive. Thanks be to Almighty God, such influences are being successfully combated; for example, by the introduction of some control in the educational institutions whereby physical education will be enforced on the student body, something that has been almost entirely neglected.

And what has this to do with ophthalmology? Much, very much; if you would have good eyes, without which a man is so seriously handicapped in the armed forces as well as in civilian life but to a lesser extent, those eyes must be in a strong and vigorous body. Such vigor can result only from physical training of the whole student body from the first

* From the Department of Ophthalmology, The George Washington University School of Medicine. Read before the New York Academy of Medicine, January 18, 1943.

grade in school to the end of the senior year in college—not from specialized training given to a few superathletes to make a team with which to advertise the university at the physical expense of the team and, worse, of the student body. A shortsighted and selfish attitude indeed.

We may not like the arbitrary methods of the military, but this very moment it is those methods that are saving this country from being overrun by savage fiends, infinitely worse than the hordes under Genghis Kahn who overran and destroyed the civilization of that day. We should be thankful, indeed, for the wisdom, foresight, and patriotism of those who established the military and naval academies, which are not excelled in the world, to give us young men trained thoroughly, mentally and physically, trained in patriotism first and thought of self afterward. Would to God our educational leaders had taken a page from history and had had the good sense to apply it to their institutions years ago. What a different situation would have presented itself now! There would have been many tens of thousands of stout fellows, well educated and disciplined; thoroughly alive to military necessity through study of the military history of our country. The educational institutions of our country have been sadly lacking in the preparation of the youth entrusted to their charge for the greatest of all tests that comes at least every generation. Because of this, certainly in part, many have been rendered physically unfit for military duty because of weak and undeveloped bodies, often with resulting defective eyes. It is our duty as members of the medical profession to combat these evil influences; it is our duty as ophthalmologists to combat the too-long hours in hot school rooms, too little physical training, and too much home work. The young people have insufficient time for out-of-doors exercise

and proper hours of sleep during their adolescence, the time they need it most. This is preventive military ophthalmology, and we should work for it and fight for it. The first graders who are suffering such insults from the schools must be the fighting men of tomorrow. Have we a greater duty than to do our best to abolish our system of faulty education and erect a sounder one in which the development of the body takes equal precedent with the development of the mind?

In speaking of delayed mustard-gas lesions, Philips² describes patients as saying that they had been symptom-free for 10 to 20 years, had continued work, and had apparently suffered no visual disability. From the onset of the delayed keratitis they experienced rapid deterioration of sight.

From a somewhat limited experience in treating eyes that have been damaged by strong alkalis and acids, it would appear that the course of disease in eyes with severe mustard-gas burns follows a rather close parallel: slow degeneration ending in phthisis bulbi. There may or may not be pain, although pain is likely to be suffered at intervals.

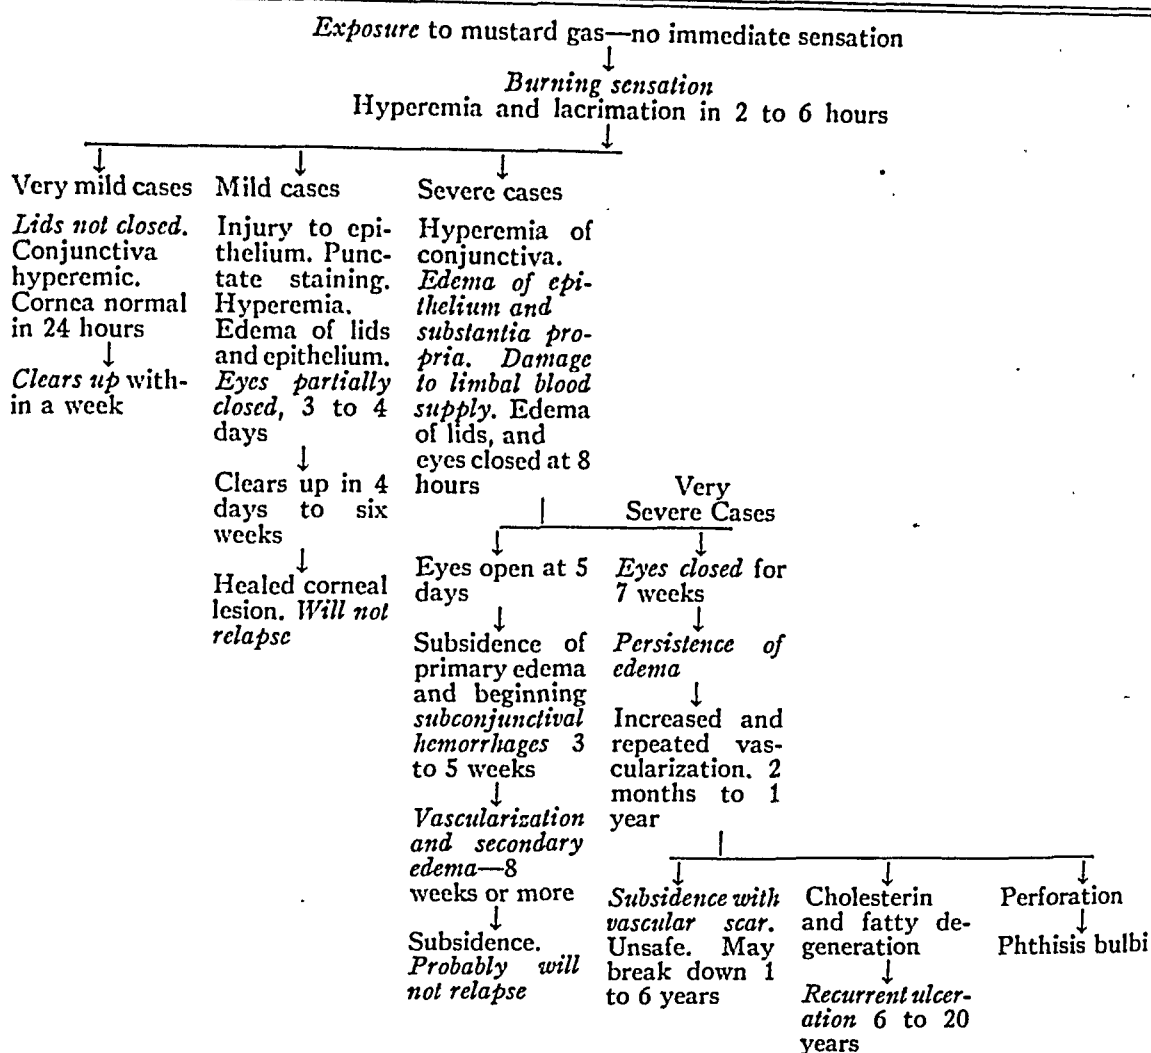

Dr. Ida Mann³ states that the clinical pathology in mustard-gas lesions in man and in rabbits is about the same. Since the life of a rabbit averages 10 years, she believes she can calculate the course of the disease following mustard burns closely in man as to time of the various developments ending in destruction of the eye. This, of course, takes into consideration the relative expectancy of life of the two animals, rabbit and man. The conclusions are as follows:

1. The clinical pathology of the lesion involving the limbus is similar in man and the rabbit.

2. The reaction in man and the rabbit is dependent on the size of the dose and the anatomic situation. The effects of

TABLE 2*

COURSE OF MUSTARD-GAS LESIONS IN MAN, COMPILED FROM OBSERVATIONS ON 65 CASES

vapor and liquid are different only when the actual amount of mustard gas that soaks into the tissues is different; that is, the difference is quantitative only.

3. The late keratitis in man is seen as a degenerative ulceration depending on the initial damage sustained by the limbus and cornea, and not on any continued action of mustard gas or any of its breakdown products.

4. From conclusion 3, it follows that, in the present state of our knowledge, prophylaxis is likely to be much more important than treatment. It is very difficult to assess the value of treatment in

man, since the dose of mustard gas received can never be known and no two cases will be comparable. Two eyes of the same patient may be comparable, though by no means is this always the case, even when the lesions are due to vapor.

EYE INJURIES

Love⁴ states in a personal communication that since our troops have engaged in only a limited amount of combat and since the statistical material has not been compiled, little information is available at this time regarding combat injuries of the eyes in the Army.

* From Mann and Pullinger. Amer. Jour. Ophth., 1943, v. 26, p. 1276.

With reference to the prophylactic measures, it was recognized early in the emergency that protective goggles were necessary for the armed forces. Consequently, a type was adopted and since that time has been furnished to all the troops in armored divisions.

About December, 1941, the War Department adopted the policy of furnishing spectacles to all military personnel that required their use. To facilitate the furnishing of spectacles and the replacements for them in the theater of operations, mobile optical units have been organized.

Steps have also been taken to provide corrective lenses for the gas mask for such troops as require them.

Lenses of plastic are being developed.

In a personal communication Matthews⁵ says that ophthalmic injuries in the Franco-German War were 1.18 percent of all wounds. In the Russo-Japanese War they were 2.2 percent. In World War I they were 5.2 percent. The percentage in this war is exceeding this figure.

Duthie⁶ observes that (1) the injuries to the eyes have, generally speaking, shown the same characteristics as those in civil practice; (2) they are mostly extremely severe types of injury; and (3) the advances made in the general treatment of casualties have shown that it is unwise to think that recovery of such severe injuries is unlikely. Meticulous treatment is indicated.

INJURIES TO THE ORBIT

When a foreign body in the orbit is giving no trouble it is wise to leave it alone. The disfiguring injuries of the face are largely in the hands of the plastic surgeon, but ocular symptoms, particularly diplopia, are of significance, as they usually indicate a more severe type of lesion. The prognosis depends on early

diagnosis and early manipulative treatment. Collaboration of the plastic surgeon with the ophthalmic surgeon is of great value.

LIDS

Every type of laceration may be seen; severe burns are the most important problem. "Tanning" does not give good results with the lids, as it is too rigid and causes too much contracture. It is better to use the gentian-violet silver-nitrate technique. Skillful nursing is necessary to care for the conjunctival discharge that frequently complicates such cases. Stelard's conjunctivo-dacryocystotomy is of much value. Early plastic repair of the lids is of great advantage and should be done where the military situation permits.

BURNS

Thermal burns are far greater in this war than ever before. They accounted for 60 percent of all casualties at Pearl Harbor. The principal factors are, according to Matthews,⁵ the ignition of oil or gasoline aboard ship; the use of highly volatile gasoline for all purposes; and the incendiary bomb and the flame thrower. The face and the hands are mostly involved. At Pearl Harbor many of the men on our ships had on only trousers. They had burns from the waist up, the face and hands and the feet, as the latter were bare. "Aviator's burn" is the term given to flash burns of the face and hands from the explosion of gasoline vapor in the cockpit. Diminution of the burns of the eyes might be avoided by the wearing of goggles. Personally, I know from service in combat with soldiers, marines, and sailors that it would be most unlikely that they would have them on at such a time and there is no time to put them on when combat starts.

The antishock gear (asbestos gauntlets and hood) is used successfully. Matthews⁵

remarks that the men object to wearing it in the tropics. I would deem it almost impossible to wear such things in combat in the equatorial heat.

Gifford⁷ estimates the extent of corneal burns by noting the transparency of the cornea and the intensity of the corneal staining with fluorescein.

General, widespread burns may coexist with the eye lesions, and the ophthalmologist should be fully informed of the procedures used in such situations.

For burns of the lids Wakeley⁸ recommends the use of 1-percent gentian-violet jelly with merthiolate; aboard British vessels it is immediately available and easily applied in combat. Suturing the lid margins is of value in assisting in the prevention of contracture and also in corneal injuries at the front. Powdered sulfanilamide becomes caked; the granulated form less so, and hence, it is better. Mixtures of sulfanilamide and mineral oil were used at Pearl Harbor with satisfaction. A 5-percent aqueous emulsion without bandaging is recommended by Matthews.⁵

An interesting fact is that sailors immersed in the sea for hours after torpedo attacks with burns, show the wounds to be clean and to heal satisfactorily. This I found to be a fact in the Moro campaigns in Mindanao. This was jungle fighting such as we are again having in those beautiful tropical isles. Our soldiers suffered from terrible knife wounds when we would be many days' or weeks' march from the coast. The wounded men would have to be carried on litters made of bamboo and rattan by the natives. Proper care could not be given; the wounds would often become infested with maggots. Upon their return to the base hospital or even to the beach I would wash these wounds in sea water; not boiled but taken from the ocean in a sterile container if one was available; often I would place the patient in the sea so that the gentle waves would

wash over him and then allow him to lie in the sun on the beach to dry. These wounds would be clean, and if it were possible to have aseptic sutures they would heal by first intention. I think sea water from clean oceans in the tropics has a valuable aseptic effect. It also is soothing, cleansing, and is isotonic with the blood serum.

FOREIGN BODIES

Matthews mentions the great differences in foreign bodies in the globe from World Wars I and II. So far in this war there is a greater incidence of non-magnetic metallic fragments due to the substitution of aluminum and magnesium alloys for brass and steel in the manufacture of bomb and shell cases. These fragments become encrusted after several days and do no harm. Ophthalmoscopically, they may resemble synchysis scintillans when they are very small and numerous.

In one series, in the Polish war, about 4 percent of foreign bodies were in the posterior segment of the globe. The typical signs were a deepened anterior chamber, depression of the iris, folds in Descemet's membrane, intraocular hemorrhage, and subsequent retinal detachment; all of the eyes with this involvement were lost.

In World War I shell fragments were the most frequent causative agents. Now with the use of the aerial high-explosive bomb, flying débris is the chief cause. In cities, glass is the most important; such foreign bodies are difficult to localize. Falling shrapnel of friendly anti-aircraft fire also accounts for many casualties. Lagrange (quoted by Matthews) analyzed the orbital and ocular wounds of the last war with the following observations. Missiles passing above the orbit, injuring the frontal bone, produced fractures in the region of the optic foramen and superior orbital fissures, causing disorders of the motor and optic nerves without injury

to the eyeball itself. Missiles passing below the orbit often produce retinal injuries by concussion, usually affecting the macular region. Where any of the orbital walls are crushed, concussion injuries of the globe are likely to occur with chorio-retinal laceration and subsequent retinitis proliferans and retinal detachment. Such detachments are rarely amenable to surgery. They differ from those detachments due to recurrent retinal hemorrhage. Proliferation stems from the ruptured choroid in the injury cases. Doherty, as quoted by Matthews, noted that unusual conditions obtained in war are: (1) spastic blepharospasm and entropion caused by irritation of the infraorbital nerve, usually from a retained intraorbital foreign body near the apex; (2) avulsion of the optic nerve; (3) enophthalmos due to depression of the wall of the orbit with consequent enlargement of the orbital cavity; and (4) hematic ring of the disc, a sequela of hematoma of the sheaths of the optic nerve.

In military surgery the size of a foreign body is likely to be larger; it is less likely to be magnetic, the period of time before treatment can be instituted is longer and sepsis is more likely to occur. It is obvious that the prognosis is worse in war injuries. It is well to put the eye to the magnet even though the X-ray picture is negative, since more than one foreign body may be within the globe. My personal experience with foreign bodies in the globe has not been a happy one. Most of the eyes are eventually lost from detached retinas, secondary glaucoma, chronic uveitis, complicated cataract, and other distressing sequelae not to mention the possibility of sympathetic ophthalmia. Many of these complications occur very late, several or more years after the injury. Removal of the foreign body may be accomplished, but even though accomplished the end results are often disas-

trous; except for iron and copper it may be best to let them remain.

SYMPATHETIC OPHTHALMIA

The risks are much greater if prolapsed and incarcerated uvea is dealt with after some time rather than within the first 48 hours. This is of the greatest importance. Eyes that have had such a type of injury and that come under observation a fortnight afterward should be enucleated if the eye looks sick and has a low-grade uveitis, is soft and with ciliary injection.

Duthie⁶ thinks eye work in general hospital suffers, being placed in a secondary position, with which we all agree. He thinks, and I am sure all ophthalmologists will agree, that injured eyes should be in an ophthalmic unit in a general hospital.

In the treatment of eye wounds in combat, which includes air raids and black-outs, first-aid workers and medical personnel are instructed to anesthetize the eye and apply sterile dressings, leaving definitive treatment to more expert ophthalmologists if the surroundings and personnel are conducive to such care.

The differences are reiterated for emphasis: Enforced delays in handling war casualties, as before mentioned, make wound contamination obviously more likely to occur. The coexistence of shock and other serious injuries may place the eye injury in the position of secondary importance. There may be inadequate or no facilities in the field. The last named can scarcely be realized or visualized by those who have not been in combat.

Our military personnel are instructed to observe the following routine in cases of perforating and other severe wounds in the field and combat.

1. Anesthetize the eye with 1-percent butyn or 0.5-percent pontocaine.

2. Gently remove any superficial foreign bodies with cotton-wound applicator moistened with boric-acid solution.

3. Flush the eye with boric-acid solution.

4. Close the eyelids and apply a fairly firm dressing, held in place by adhesive tape.

5. Evacuate as rapidly as possible, so that the patient may receive proper ophthalmologic care promptly.

6. Do not close the wound with sutures.

7. Do not excise any tissue protruding from the wound.

8. Do not cover the eye with a conjunctival flap, unless specifically equipped to do so.

Two German writers are said to have successfully sutured corneal wounds with human hair. They claim better optical results than with a conjunctival flap.

When an eye is destroyed, and bits of uveal tissue are buried in the surrounding tissues, they should be sought for and removed to prevent sympathetic ophthalmia. Early probing in the orbit for bullets or shell fragments is unwise. Infection may be introduced into the orbit or through skull fractures to the meninges.

Grossly lacerated lids may be sutured over the cornea to prevent drying of the latter. Walker, quoted by Matthews, introduced sulfanilamide crystals directly into the anterior chamber in severe lacerations of the cornea at Pearl Harbor. This was done before closure with a conjunctival flap. The results were gratifying. All army personnel carry into combat packets of sulfanilamide on their persons and are instructed in its use.

CORNEA

Multiple foreign bodies are the most important and the most frequent injury. Subconjunctival foreign bodies had best be let alone. They usually work to the surface; if not, they rarely cause trouble.

If the eye is quiescent when there are numerous foreign bodies in the cornea, it

is best to let it alone rather than attempt complicated or even simple methods of removal, since no irritation is present. Subsequent sepsis is rare. Even if the eye is considerably injected as the result of the explosion of an incendiary bomb, for example, too much interference is probably unwise.

CONCUSSION

Concussion is frequent and is the result of (1) direct blows on the eye, (2) blows on the bones of the face or orbit, (3) foreign bodies traversing the orbit, and (4) blast.

These were the most frequent injuries of the last war as of this one, and there is voluminous literature concerning the subject.

The various conditions arising from such injuries are iridodialysis or, conversely, rupturing or tearing of the pupillary margin; concussion cataract; all types of intraocular hemorrhages; retinal-concussion changes characterized by large areas of dark hemorrhages; ruptures of the choroid, concentric to the disc, or, more occasionally, a tear radiating from it, and avulsion of the optic nerve.

Intraocular hemorrhages are important; if they are anterior and persistent, secondary glaucoma may supervene. Paracentesis of the anterior chamber is in order. Posterior hemorrhages are sinister. Efforts should be made at once to favor absorption and delay coagulation, thus preventing the formation of solid masses in the vitreous which resist absorption. They may become organized.

A solid clot may cause false light projection although there be no lesion of the retina or choroid. This may lead to the enucleation of an eye that might have the possibilities of restoration of vision.

The patient, according to Duthie,⁶ should *not* be kept in bed but should move about. After a considerable period, if ab-

sorption of the clot is not taking place, scleral puncture may be considered. Subconjunctival injections of normal saline may be tried.

RUPTURE OF THE GLOBE

The majority of cases are caused by flying splinters and glass. Many globes are completely destroyed; many hopelessly injured. Personally, I think we should make a careful inspection and a more careful decision where there seems to be even a faint hope of saving the eye.

There may be rupture by contrecoup or rupture caused by a foreign body penetrating into the orbit but not the globe and causing rupture by striking the eye itself. If the uvea is extruded it should be cut off. In cases in which there are severe wounds in the ciliary region, in unilateral cases, and in those presenting other intraocular complications, Duthie advises enucleation. This is good advice when we consider the possibility of sympathetic ophthalmia. Nevertheless, I think we should be conservative *where military conditions permit*.

Small conjunctival flaps sutured firmly to the episclera I consider to be better than large ones and also better than scleral suture.

Like myself, Duthie is conservative in the use of sulfa drugs in cases of intraocular sepsis or the prevention thereof. All other aseptic and antiseptic precautions should be followed. The end results of ruptured globes are most frequently very sad in military as in civil practice, and this is the experience of us all. They are likely to be sadder in military medicine than in civil practice for obvious reasons.

It appears best, in the combat elements of the army active in the field, to bandage the injured eye and get the man back to the nearest place where adequate treatment or enucleation can be carried out. This applies to all injuries of the eye of

any moment, except gas injuries, where bandaging is contraindicated. Obviously, the treatment of more than trivial injuries cannot be adequately carried out in a fast-moving combat force. It would seem that the wounded and injured, under present combat conditions, may have to wait long and travel far before they may receive adequate treatment. In the days of marching armies, wagon trains, and no air strafing, the field hospitals were relatively easy of access. Today they may be hundreds of miles away and accessible only by air or rapid motor transportation. There may be no such transportation available for the wounded. Combat calls for everything the army has when a battle is on. The regulations state that so much transportation will be available for the medical department. This is under the direct command of the ranking general, not the medical officer, and he has to win the battle or all are lost, wounded included. Under such conditions the theoretic transportation may be unavailable for a time; hence, it is every man to his job to do the best he can under the worst possible conditions, lack of food, water, shelter, and supplies.

In a personal communication from Dr. Meyer Wiener,⁹ honorary consultant in ophthalmology to the Navy, he says:

"I think one of the striking features about foreign-body injuries in this war is the fact that we have not had a single one that was magnetic. Even when they were removed, and looked like iron or steel, they failed to be attracted by the magnet. An analysis of quite a few proved them to contain a large amount of copper. Then we have had a number that looked like aluminum and proved to be such when we had an opportunity to test them. We make no effort to remove aluminum, as it has proved to be harmless, thus far. We had one officer who had multiple fragments of aluminum all over his body, including some in the knee joint, which had to be removed. These were sustained while in action on a destroyer on August 7th during the first battle for the Solomons. One penetrated the left eye. You could see the tract through the cornea, hole in the

iris, tract through the lens capsule and the foreign body in the lens, just above dead center. We left it in. The patient has had no irritation whatsoever and his vision in that eye today is 20/20-1.

There is another boy from the Solomons who had one eye shot out, with multiple fragments in the right eye, some opacity in the lens, bands in the vitreous, and much blood. We have also treated that expectantly, and his vision has gradually crept up from bare perception of light with poor projection, to ability to count fingers at 6 inches and increasingly improving light projection, tested with the lids closed.

As in the last war, we have seen injuries to the retina and rupture of the choroid from concussion, without any visible external involvement. One case was seen recently with a double rupture of the choroid. The worst cases are the ones where the eye has been penetrated by large objects, especially in the ciliary region. Most of these have had to be enucleated. There have been a number of lid injuries which have required plastic repair. Thus far, we have not had to reconstruct any by pedicle grafts. Dr. Lucic got a beautiful result in a case where the lower half of the right upper lid had been burned away by molten metal, by transferring a segment from the opposite eye, including a thin margin from the brow, and reversing it so as to make a row of lashes. I acted as his first assistant. You may recall him as he was at Wilmer Institute for several years before coming here. I think it should be stressed that the all-important thing is to give adequate proper immediate care, which would obviate the necessity of doing many plastic repairs. We had one recently which demonstrated that. We worked on it for over two hours but finally did get a most satisfactory permanent result. Of course, one cannot always do this under actual battle conditions; but it is my belief that if they do not have the time or conveniences, they should clean up things as best they can, do no débridement, and let the fragments fall as they will. They can then be separated later and readjusted. This is naturally only second best.

I think that you should bring up the subject of malingering. Perhaps some of these fellows are not really trying to gyp the Government, but are shell shocked. At any rate, they must be considered, as we have a lot of them. They are easy enough to catch when only one eye is involved; but when it is claimed that both are affected and equally so, it is a different matter. We have one now, who I am convinced is a fakir but feel that he has been so well coached that we are going to have a hard time proving it.

I thought you would be interested in one case we had of arteriovenous aneurysm of the lateral sinus, with marked proptosis, dilatation, and

tortuosity of the vessels, both externally and retinal. Dr. Leonard Furlow tied off the internal carotid, and the swelling is about gone, with almost normal vision. This case was due to concussion but there was no external injury."

Major W. Randolph Lovelace, II,¹⁰ at Wright Field, in a personal communication says:

"The latest work that is being carried on in the Air Corps is that on night vision, color vision, depth perception, and the approaching possibilities of revamping visual requirements for pilots to the lowest limits, commensurate with good performance, rather than the highest possible limits. As far as this laboratory is concerned, I am sure it would be all right to mention the fact that an apparatus is being developed to determine accurately and quickly the degree of night vision present in all flying personnel and that oxygen equipment is being designed so that it can be comfortably used in conjunction with Air Corps goggles. Color vision, of course, is important from the standpoint of detecting camouflage and from the standpoint of night operations."

The different branches of the service naturally have different eye requirements. Those of the Air Force are the most severe, as one would imagine. Incidentally, this leads on to this interesting corollary; there are many investigations and original research problems as well as the results of practical experience which are adding a great deal to our knowledge of the visual act. It is not proper to speak of many facts which have been discovered but they pertain to color vision, night vision, anoxia, and high-altitude flying, and the results on the visual act as to visual acuity both central and peripheral, and disturbances of ocular motility. Much study has been done on dark adaptation. Its importance lies in the necessity for keeping the eyes of the men in the fighting air force dark adapted all the time when they are on duty. It appears that by having them wear red glasses, the dark adaptation is not interfered with and they can see sufficiently well to read while waiting for the call to take off. I am informed that

illumination of the cockpit by red light is better than the "black light"; that is, ultraviolet light acting upon fluorescent dials on the instrument boards.

Dark adaptation and night blindness have received much attention and practical study since the beginning of the war. Much of practical value has been determined. Knowledge of dark adaptation, light sense, and light differences are of great practical use even though the laboratory methods are not satisfactory. Attention is directed to the Military Surgical Manual,¹¹ where the writer speaks of night blindness and uses the term "war hemeralopia" as applied to soldiers. This did not occur in our Army but did in the armies of Europe who were half starved, as was the whole population, as it is again today. It is, of course, due to avitaminosis A and is curable by the exhibition of this principle when it is available. This manual also deals with diseased eyes with poor night vision and also malingerers and neurotics. Those with diseased eyes would, of course, be quickly discovered and eliminated. Malingerers are subject to court martial and severe punishment, and neurotics do not long exist in a military force. My long military experience taught me this. Malingerers do not last very long when they get into the hands of their comrades, who know full well how to handle them. Incidentally, a good stiff top sergeant is the best cure I know for a neurotic.

FACTORS AFFECTING NIGHT VISIBILITY¹² (Military Surgical Manual¹¹)

A. PURPOSE

For night operations it is essential that troops be trained to avail themselves of all existing means whereby night vision and the ability to observe are improved. All individuals do not adapt their eyes to darkness at the same rate of speed. It is therefore desirable that commanders

know what persons within their organizations have faulty night vision. The ability to see well in the dark is improved by systematic training.

B. FACTORS INFLUENCING DEVELOPMENT OF DARK ADAPTATION

1. The time necessary for dark adaptation can be shortened by avoiding bright lights prior to going into darkness.

2. Lack of oxygen markedly decreases the ability of the eye to adapt to darkness. At an altitude of 16,000 feet this reduction is such as to require 10 times as much light to see an object as would be required by the same individual at ground level. Even at 4,000 feet, impairment of night vision is noticeable. Crews of night fighters who are climbing fast should take oxygen from ground level if they wish to make the best possible use of their vision on dark nights. More oxygen than that normally required will not further increase night vision.

3. Persons suffering from a severe lack of essential food factors (vitamins) will show a diminution in their ability to adapt to darkness. In these cases, resumption of an adequate diet or the feeding of vitamins A and D will return the night vision to normal, but an excess of these vitamins will not further improve night vision.

C. FACTORS INTERFERING WITH MAINTENANCE OF DARK ADAPTATION

Eyes adapted to darkness will remain so only in the absence of interfering lights. Such a condition, however, seldom pertains in warfare. Light interference may be of many sorts: dash lights, searchlights, gun flashes, flares, and reflected moonlight. Individuals must be made to realize the necessity of avoiding the effects of such factors. Conditions in the combat zone usually dictate that motor movement be made without lights. When

lights are allowed, drivers of motor vehicles should be especially instructed to keep lights within the vehicle at a minimum and to take only fleeting glances at instruments.

D. OTHER FACTORS AFFECTING NIGHT VISIBILITY

1. Any form of distraction will result in a less efficient observer. Outstanding among these are the discomforts occasioned by cold, noise, and objects interfering with the field of vision. Fatigue tends to inattention and greatly interferes with night observation.

2. Reducing the contrast between an object and its background detracts from night vision. Anything which scatters some of the light, such as a scratched or dirty windshield, has this effect.

3. In dim lights a large object may be visible when a small one is not. For this reason, night binoculars, designed to admit as much light as possible, help night vision by increasing the apparent size of the object. The use of night glasses is restricted by the fact that they limit to some degree the quantity of available light rays reaching the eye, restrict the field of vision, and must be held without vibration.

E. TRAINING IN PROPER USE OF EYES

1. In daylight objects are seen most clearly with the center of the eye but at night this ability to see images most sharply shifts to a position slightly off center. For this reason, during darkness the gaze should be directed about 10 degrees to one side of the field that is being observed.

2. The eye is also subject to fatigue. An object will be most distinct immediately upon looking at it. If, however, the gaze remains fixed upon the particular object it gradually loses its distinct outline and blends with the surroundings.

3. Night observers should be taught to

employ a roving movement of the eyes in a series of short jumps. Nothing can be seen while the eyes are actually in motion, but vision is best just after they have been moved. This fact is of special significance to the air observer. Rapid changes of angle of bank, producing this effect of rapid motion of the eyes may result in failure of a pilot flying a night mission to see an object on one side of his line of flight.

F. TEST FOR NIGHT VISION

1. The following rough measurement of night vision may be made by testing men outdoors on a dark night before the moon has appeared. A night will be considered too bright for test purposes if, after 25 minutes of dark adaptation, individuals can read small newspaper type without the assistance of light.

2. Mount on a post at the end of a level space 5 yards wide and 40 yards long and away from all artificial light, a black target on which is a movable white strip 6 by 24 inches. Mark off distances from the target at 5-yard intervals. After the person to be tested has been kept away from all artificial illumination for 25 minutes, direct him to walk slowly from the far end of the test area toward the target. The distance at which he is first able to identify correctly the position of the white strip is noted. While the person being tested is walking back for another trial, the position of the white strip is changed. Several trials are made. Correct recognition should take place at an average distance of not less than 20 yards from the target.

G. SUMMARY

1. Instruction designed to improve the ability to observe in darkness will include training in the proper use of the eyes at night and a consideration of those factors assisting or interfering with night visi-

bility. The following points will be especially stressed:

- a. The importance of and factors governing pre-adaptation.
 - b. Proper methods of search and the employment of "off center" vision.
 - c. The detrimental effects of night adaptation of: (1) lack of oxygen at high altitudes; (2) light on the dark-adapted eye; (3) distraction, with special reference to cold, noise, and objects interfering with the field of vision; (4) fatigue; (5) light dispersion, emphasizing the necessity for scrupulously clean windshields.
2. Unit commanders will identify those individuals within their units who possess decreased ability to adapt to darkness, in order to avoid the hazards incident to the injudicious employment of men whose night vision is below the average.

AVIATION MEDICINE

The study of the new field of aviation medicine reveals some new facts but mostly known facts widely extended. It is a specialty within itself in that it requires considerable knowledge of several specialties, some of them quite highly technical; for example, like ophthalmology and otolaryngology.

To quote from the Technical Manual,¹² "A defect which may be considered as minor or insignificant in the ordinary walks of life may be serious indeed for the pilot of aircraft." I might add, that we cannot be too careful in these examinations; a slip might cost the lives of all in the plane, the plane itself, and, it is quite possible, the lives of many in the army on the ground. To quote again:

"In all probability there is no other type of physical examination where the time element is so important, where the adage 'make haste slowly' applies more forcibly. A complete ocular examination is at best a tedious procedure and requires an infinite amount of patience on the part of the examiner and the examinee, and, where 'short cuts' are employed or de-

cisions made hastily, the accuracy of the finding is at best questionable. The eye examination should be objective as far as possible. Obviously the type of examination given for this purpose differs greatly from the examination given for clinical purposes. To the trained ophthalmologist, the eye examination is very simple, yet one has to use care that because of its extreme simplicity one does not become careless. This is a small matter, however, since relatively few trained ophthalmologists will be giving these examinations."

Fourteen steps are outlined on page 69 of the Technical Manual in the examination of candidates for flying training in the air service. It might be well to note them: Visual acuity, depth perception, Maddox rod with screen test at 6 meters (please note that it is the rod and screen test, otherwise serious errors will creep in), red-glass test, prism divergence, prism convergence and associated parallel movements, inspection, pupils, accommodation, angle of convergence (not P_cB), central color vision, fields of vision, refraction, and ophthalmoscopic examination. It will be noted that this is quite a comprehensive examination for a physician who is not an ophthalmologist. Thus, special training is in order for the flight surgeons.

With the enormous number of flight surgeons required it would seem that perhaps the civilian medical schools and the eye hospitals could greatly assist the armed forces in this rapid education in the basic requirements in ophthalmology, which composes the most highly technical division in the subject of aviation medicine.

COLOR VISION

In the matter of color testing and color vision, more instruction should be given in ophthalmologic training. A number of flying personnel are passed by the medical examiners who are "color unsafe." A number of cadets are admitted to West Point whose color vision is defective. This situation is exceedingly dangerous and

slows down the war effort. Likewise, it is casting an aspersion on the medical profession. There is some slight excuse for it in that, so far as I am aware, there is no clear-cut and decisive outline of a method to be used in testing color vision. There are no standardized nor accepted criteria upon which to work. The confusion in the terms used expressing color vision and deficiencies thereof is confounding. Nevertheless, the young ophthalmologist should be taught and required to know the subject well enough to make an efficient color-vision test for the services and to make a proper diagnosis of the deficiencies expressed in proper terms. It would be a real help to the armed services if a pamphlet could be forthcoming expressing briefly, succinctly, and practically, the essentials that the doctor of medicine, making such tests, should know about color vision. Anyone who attempts to inform himself encounters theories as to how color perception is perceived, or different terms meaning the same thing and the same terms meaning different things. Those among you who have not experienced military service can scarcely appreciate what a boon it would be to the armed services, and hence to our country in time of need, if something that is practical and definite could be given to the doctors going into the Army and Navy. A quick and efficient method of testing color vision is a great need. Tests requiring extensive expenditure of time often mean hasty and inefficient examinations and faulty findings.

WAR OPHTHALMOLOGY

War ophthalmology differs but little from that of civilian life. The *facilities* for taking care of eye injuries, however, differ greatly. The utmost ingenuity must be exercised by the surgeon in overcoming the difficulties of the situation.

Vail¹³ mentions in an editorial that at

base hospitals a thoroughly trained ophthalmologist should be stationed with equipment necessary for extraction of foreign bodies from the eyes and all other care of the injured, sufficiently serious to be returned to the base. This is a problem which has not been answered as yet as to how the wounded that require hospital care can be gotten to the base. I have not the slightest doubt that the medical departments of the Army and Navy have formulated in minute detail the plans for such care. *But*, they are probably largely on paper. Having gone into a world war with probably almost total lack of anything approaching adequacy, good sense will tell us that the medical department of the Army has found it physically and humanly impossible to prepare properly against the vicissitudes of troops in the Arctic, on the Equator, and in the burning deserts, all requiring the greatest difference in the handling of such a colossal problem. How are men with seriously wounded eyes to be transported to a base that in order to be free from bombing has to be possibly a thousand miles away, or across seas, from the combat area? Here can be accomplished the plastic work for restoration of appearance and function, both of almost equal importance. The importance of adequate first aid in the combat zone to prevent infections, of rapid transportation and care en route of the wounded to the base, requires the almost perfect coördination of many departments of the army. With an army suddenly expanded from what was merely a national constabulary in *point of size* to one of many millions, the result has been a dreadful lack of officers with military experience, discipline, and training. It cannot be otherwise but that confusion, inefficiency, and slowed-down transportation will result in combat areas. It is inevitable that many of the wounded will be a long time reaching the base, and

that first aid is all they will get for some time. Such is the price our fighting men have always paid for unpreparedness.

The laboratories throughout the United States in the Army and Navy are originating and constantly working on relatively nonbreakable substitutes for glass. Much progress is being made. Plastics and resins are being utilized for lenses with some success. They are relatively unbreakable, which is a very great advantage, but they have other physical characteristics that are undesirable. For example, they are soft, and hence scratch easily; they do not retain their shape, and hence the dioptric strength does not remain constant, or the material becomes discolored by brilliant light and is less clear.

It is obvious that a substitute for glass for ophthalmic and other lenses for windshields and windows for airplanes, and so forth, which has not the above-mentioned disqualifications, will be of the utmost value.

Despite our criminally shortsighted preparation for war, which has heretofore been as inevitable as death, I think we are better prepared than in former wars, but relative to the remarkable preparation of our enemies, I doubt it. Vail invites attention to the suggestions of Sir Richard Cruise that 50 percent of the eye injuries could be prevented by some form of eye protection. The officers of the combat services say vision is impaired by such protector devices. The line officer is correct but that is only one of the reasons soldiers go into battle without many of the protections they might, could, or should have. These soldier lads have to carry it all on their backs. Only those of you who have been in battle can realize what that means, fatigue near to exhaustion, hunger, thirst, intense heat or cold, a weariness of soul and body which no civilian can understand, with a battle at the end of it. He throws everything away

he has but his fighting tools, and no officers can stop him nor do they try. Sir Richard was correct but his viewpoint erroneous. Foot soldiers have always so stripped for battle; otherwise their fighting efficiency is much impaired and, of course, that cannot be.

AVIATION OPHTHALMOLOGY

Major Weaver¹⁴ in a personal communication states that high velocities, high altitudes, low oxygen tension, even when using an artificial oxygen supply (extreme cold, minus 68°F. at 35,000 feet), and reduced barometric pressure, together with night flying for combat observation and bombing, have created a number of new and basic problems, the most important one perhaps being fatigue. These problems have been studied for years by foreign powers, but in our own country not until very recently have laboratories and other facilities been available for our army to make the studies so urgently needed to solve these complicated and diverse matters. It is obvious that a group of men in many special branches of science are required to study these matters and the facilities of thoroughly equipped laboratories are necessary. In our country no adequate group of scientists or laboratories was available until about the time or shortly after the enemy had attacked and seriously crippled us. We were wasting billions of the people's money in political works administrations but only a trickle for that essential necessity for our national safety—scientific study of war and in preparation for war.

Many studies have been made since the recent facilities have been supplied but there are so very many which have not been made because of lack of time. We know research cannot be carried out hurriedly.

According to Weaver, "the factors peculiar to aviation which influence vision

may be listed as anoxia, decreased barometric pressure, temperature changes, acceleration, fatigue, nutrition, physical fitness, and certain drugs."

As to *anoxia*, it would seem that the direct effect upon the eye is closely related to the effect upon the central nervous system, the cerebrum in particular. Since the visual part of the eye is an integral part of the brain we may assume this to be true. Cerebral function is less effective and slower, depending upon the degree of anoxia, and so is vision. Visual acuity and color vision are lessened; perhaps the latter is obliterated. Night vision becomes less efficient. The visual field is reduced in size. Fatigue of the nervous system and, in consequence, of the whole body ensues.

Toxic states, resulting from infections, drugs such as the sulfa drugs, alcohol, and so forth, render the flyer less efficient. The toxins of fatigue, which occur naturally more promptly in those not in "hard" physical condition, also greatly contribute to early lessening of the efficiency of the flyer. No doubt the "poisons" of civilization must contribute to this condition; I refer to tobacco, tea, coffee, and alcohol in excess.

Is it not obvious that the best preventive of eye disabilities for the armed services and in particular the air forces of these services, is a strong body, a strong mind, and a pair of strong eyes for that strong body and mind to see with? Isn't it equally obvious that in order to have this, the physical training of these youths should begin at the beginning of life? When they enter school it should be continued and given equal value with mental training. If this had been done by the schools from the primary grades to the end of high school and by the colleges from their freshman year through the senior year, would we have so many lads disqualified for the air forces because of myopia and undeveloped bodies? I think not. Why did

the schools neglect our youth? I do not know the answer. Do you?

Long-continued anoxia, even of low degree, leads to cortical changes, which though irreversible may be subclinical because of the great number of reserve cells in the cortex; similar changes may be inferred in the eyes, particularly in the ganglion cells. It is stated that the time required for irreversible changes in the cortical cells in acute anoxia is from 5 to 7 minutes.

As of this date, I am not aware of observations or experiments showing the effect of anoxia upon color vision. One must assume it is profound. According to Weaver, pilots have reported their color vision dulled as noted in signal lights after high-altitude flying. The lack of accurate knowledge concerning color vision prevents the acquiring of necessary information by observation and experimentation.

It is unfair to assume that those who have slight color-vision deficiencies may be dangerously low in color perception in the presence of anoxia, even of low degree. We are more aware of the effect upon the motor functions of the eyes—accommodation, the vergences, and the highly associated movements of the eyes—all of these may be disturbed. Minor motor anomalies may become serious major ones. I have observed a number of cases of exophoria due to divergence excess in those who have been flying for several years. They had been carefully examined before being given the responsibility and at intervals since. It has seemed to me that it has been acquired since they began regular flying and spending long hours at moderate airplane altitudes, 8 to 12 thousand feet. The majority of cases I have seen are not due to convergence insufficiency but to divergence excess. Could the anoxia, coupled with long-distance vision in which the divergence is presumably under a strain, have

a bearing on this? It is a fascinating hypothesis. We know, of course, that vertical phorias are less amenable to control than the lateral ones. Exaggeration of these vertical phorias, by anoxia, could disorganize binocular single vision very quickly and very effectually. Our knowledge of the effect of such disturbances upon convergent squint and less perhaps upon divergent squint will enable us to understand this easily.

Quoting from Weaver, who quotes Rickenbacker during the first World War:

"Another of those little precautions which might spell the difference between life and death, was the habit I forced on myself, always to make two complete circles of the landing field before landing at the end of a patrol from 15,000 feet."

He had observed that his landing ability was impaired; this is due to a number of causes, impairment of the depth perception being perhaps the most important. Weaver states,

"Vertical deviations are of the greatest importance in landing since, with such displacement, depth perception which results from fusion and consequent stereopsis is not only lost entirely but if the flyer lands according to the information furnished by the falsely projecting eye, he may land high or fly his ship into the ground. In the air, under combat conditions, similar misinformation under conditions of anoxia may lead to equal danger."

We remember that a latent deviation becomes manifest and exaggerated under anoxia and becomes a complete tropia with diplopia or monocular vision due to suppression of the vision of the deviating eye. Fatigue, profound emotional disturbances, the unusual ocular conditions of flying will all add to the motor weakness.

Anoxia definitely slows dark adaptation. Long-continued subclinical anoxia or the cumulative effects of anoxia have not been exhaustively studied. Cold does the same thing. It has been observed that in

exposure to extreme and long-continued cold the effects upon the nervous system are very similar to those from anoxia and are probably due to anoxia from the slowing of the heart and, hence, of the blood stream. It is thought that this is the cause of the extreme somnolence that overcomes those approaching death from freezing. In anoxia it is probably, Weaver infers, that the synapse is altered in the retina and in the tracts from the visual cortex to the extravisual cortex.

The importance of night vision and combat aviation are stressed by Weaver. He emphasizes, on the one hand, the use of the macular retina and cone vision for daylight and color vision and, on the other hand, peripheral retinal or rod vision. The rods serve a colorless task in daylight and register movement and large objects. At night when dark adaptation has taken place and illumination is by the stars, the rods are the more active. They locate the object of low light intensity. When, however, fixation is shifted to the macula, the image disappears because the cones have a much higher threshold for light than do the rods. "Rods are one thousand times more light sensitive than cones under conditions of dark adaptation," says Weaver.¹⁴ "They do not distinguish color but only degrees of brightness." At present it appears that the complete serial values of cone and rod vision, under dark-adaptation conditions, are not so important in classifying the night vision of an individual as is the calculation of rod-threshold value after a time interval in the dark of 30 minutes. Obviously, in aviation the light threshold of peripheral vision is by far the most important factor.

Rods do not see colored light in their corresponding colors but only as white light of different degrees of brightness.

Consider three lights to be of equal intensity, blue, red, and white. Using "pho-

toptic vision"—that is, "day eyes"—the white or red will appear brightest and they will be recognized as different colors. "But let the individual see these lights from a great distance under conditions of dark adaptation, such as the pilot lights of an enemy plane, the blue light can easily be seen; the white light is 1/10 and the red light is 1/100 of the blue light's brightness." The red light will not be seen at all under such conditions. Obviously, as Major Weaver writes, the blue light is the most dangerous as a blackout light and red the least dangerous. This is a matter of great practical interest to ophthalmologists.

Night vision may be materially retarded by anoxia and a reduction or absence of vitamin A. It must be remarked here that giving vitamins to a normal person does not improve his night vision.

In *changes in barometric and temperature pressure* a great many new and difficult problems have arisen. Because of the cumbersome helmets, oxygen masks, and goggles, vision may be interfered with to a very marked degree. There are a myriad of mechanical failures of the apparatuses to supply oxygen and heat to the pilot in a temperature of minus 68°F., and low barometric pressure at 35,000 to 40,000 feet. All these make efficient seeing difficult and inefficient but can be corrected only by improving the mechanical arrangements necessary for sustaining life at such altitudes.

Acceleration (speed), particularly angular acceleration—that is, as encountered in the pullout of a dive—precipitates in some flyers the "gray out" which warns of the imminence of "black out" or unconsciousness. These phenomena are dependent upon habitus and physical fitness of the individual, the length of time the physical forces act; the number of G's (units of gravity). The latter is directly proportional to the velocity of the plane

and inversely to the radius of the executed turn.

"It is not known whether the factors involved are cerebral ischemia with resultant cerebral anoxia alone or whether the differential between the pressure of the cerebral and retinal arteries is of importance" (Weaver¹⁴).

FATIGUE

Of all the subjects discussed, none is more important to the pilots than efficiency of vision. The first and most important factor is the pilot himself; how good a man is he? How physically fit is he? Has he any inherent physical or neural weaknesses? We have discussed the most important contributing causes, anoxia, acceleration, and combat; also the mechanical appliances, goggles, masks, and so forth, all reducing efficiency. They fret and worry the pilot and this contributes enormously to fatigue. Goggles with a common glass for both eyes do not so reduce the nasal visual fields nor the binocular field of vision. In such a goggle, removable plastic lenses of different colors may be utilized. Plastic lenses, being fire resistant and non-shatterable, protect the eyes in a crash and also against fire, the latter being particularly important in the "flash" fires of this war. In various naval engagements the number of eyes badly burned from the "flash" fires (the blast from an exploding shell, a gun or bomb, or explosion of gasoline in a confined place) has been considerable. Tremendous heat is generated for a fraction of a second. Also many eyes are injured by swimming in oil-covered seas. This appears to cause a severe conjunctivitis and in some cases mild keratitis. So far as I am aware no permanent injury has resulted from this cause.

The use of heavily tinted glasses is really necessary under certain conditions of flying. Flying above the clouds produces

the most intense glare from below; the sun from above is a different sun from the one we see from the earth, much more powerful and intense. The combination of the two is very trying and very fatiguing even to the strong normal young eyes of pilots and requires protection.

Major Weaver¹⁴ mentions an interesting fact in connection with drugs of the amphetamine type, stating that Axis pilots are believed to be well supplied with such drugs. It appears that the advantages outweigh the disadvantages. One may understand how the nervous system may be whipped up for a temporary exploit. In time of stress, it might be advantageous. It would appear that abuse of such drugs might occur and that their use should be attended with great care. Any drug stimulating the nervous system naturally accelerates vision and the whole visual apparatus temporarily.

It is unnecessary to consider before a gathering of ophthalmologists the minor injuries to the eyes. Their treatment and disposition are the same in civil life except certain modifications in the military service which will suggest themselves to the ophthalmic surgeon.

Burns from heat or caustic agents require care that often cannot be provided in combat and probably for some time afterward. It is useless to think of special solutions; if one has water from his canteen he is fortunate. The crudest possible arrangements may be contemplated and met with where the good sense of the surgeon and the skill in his hands will be about all that he has to work with. It may be that all we have with which to wash the eyes is water from a stream or a water-containing plant. Such plants are often encountered in the tropical jungle—the rattan vine, for example.

As to neutralization of chemical burns, this is practically impossible and in mili-

tary life would probably be utterly so. Prompt removal of excess alkali or acid by copious injection, should fluid be available, is desirable.

My experience in the jungle fighting in Mindanao, Bataan, and other parts of the Far East (which is far no longer) enable me to say that if you have any medical supplies it will be due to your fighting spirit that you obtain them and to your physical vigor if you have them in combat. I mean that you, yourself, personally, may have to carry them on your own back into the fight. Hence, it is idle to talk of having for first aid this favorite prescription, or that favorite irrigant. At the field station, if one is at hand, more adequate first-aid treatment may be had.

Gas burns in military life, when they do occur, are sudden and in great numbers, and only the most casual first aid is possible as a rule. We are familiar with sodium-sulphate solution (0.4 percent) for use in tear gas burns. For mustard-gas burn, use copious irrigation as promptly as may be possible; if available, 1.5-percent solution of sodium bicarbonate, saline, or boric-acid solution. Five-percent sulfathiazol ointment is advocated in cases of severe burns. I have had no experience with this.

Lewisite is probably more destructive than mustard gas. I am not acquainted with its late or latent effects as compared with those of mustard. Copious irrigation and subsequent symptomatic treatment are all that can be given.

We should bear in mind that contusion of the globe may follow explosions, mines, shells, bombs, and so forth, without much obvious damage to the external tissues and be prepared to deal with the many complications and sequelae which arise as a result of such injuries.

It would be well if all, not technically informed, should thoroughly familiarize themselves with local anesthesia for all

ophthalmic operations. General anesthesia may be impossible or difficult to have administered. There are no operations upon the eye or adnexa that cannot be performed without severe pain if the methods of securing anesthesia by infiltration or nerve block are adequately known and followed. This statement applies to civil

life as well as to military life.

It is interesting to remember the War Manual Number 3, written by Colonel Greenwood, Colonel de Schweinitz, and Colonel Walter Parker, which would be perused with profit by any of the doctors going into military service.

EMILE JAVAL*

AN APPRECIATION

BURTON CHANCE, M.D.

Philadelphia

From the list of subjects in which your committee suggested you might be interested, I have chosen the name of one for whom I have profound admiration. It is that of Emile Javal, known to us as an ophthalmologist, but, to his countrymen he was also a hygienist, a politician, an educationist, and a social reformer. By his death, our profession lost a very distinguished member who, at that time, was known throughout the world as one who had taken an important part in modern ophthalmology.

Javal was born in Paris, May 5, 1839, and, at his death in his native city, had reached his 67th year. Possessing an unusual and active mind, from his boyhood he was attracted by every problem, physical or biologic, that came his way. He had wished that he might enter medicine, but was trained as a mining engineer. He became interested in the case of his small sister who was cross-eyed and amblyopic (strabismus had been a distinctive feature of several members of his family, including his father). For her he conceived the idea that by means of a stereoscope, binocular vision might be developed. The results which she attained from her brother's perseverance during several years reached a degree of development sufficient to convince him of the value of his observation. Impressed by that result he decided to abandon engineering, and forthwith took up medicine. Having his sister's case in the background of his mind, he early began to give his special attention to diseases of the eye. For a pe-

riod he was one of von Graefe's pupils.

With the outbreak of the Franco-Prussian War in 1870, he entered into the service as a military surgeon, and continued therein until the end of the war. He then returned to his chosen field of practice but, having espoused decidedly liberal ideas, he began to interest himself in political affairs. In 1875 he was elected to the General Council of the nation, representing a county district. Later, gaining a seat in the Chamber of Deputies, he became noted both in the Tribune and in committees. All this, however, without interrupting his professional work. M. Zola received much inspiration for certain of his works from Javal's interests and knowledge, and during the Dreyfus trial Javal went to Rennes and exerted himself on the side of the accused.

In the meantime he translated into French, Helmholtz's "Physiological optics"; continuing with energy and ingenuity the study and treatment of strabismus, the result of which he published in 1896, a "Manuel theorique et pratique du strabisme." It may be stated that through Javal chiefly have we learned that the faulty vision of the squinting eye frequently may be improved and that, by dint of compulsory education, through practice with stereoscopes and other educative exercises, the power of fixation may be acquired and true binocular vision established even in long-untried cases. Javal, accordingly, may be counted the patron saint of orthoptics. He warns us, nevertheless, that the time and trouble involved in achieving good results are out of all proportion, sometimes, to their value at the ultimate attainment.

* Read at the annual dinner of the New York Society for Clinical Ophthalmology, Tuesday, May 25, 1943.

In addition to these particular subjects, he was a persistent advocate of reforms in the hygiene of schools, especially toward the conservation of the sight of children.

My first knowledge of Javal was gained while inquiring about a well-worn instrument, called an "ophthalmometer," which I saw at Wills Hospital while still an undergraduate. It is such an instrument with which Javal's name is more definitely connected than with his extensive work on strabismus. The principle of the ophthalmometer consists in affording means for the measurement of the curvature of the cornea and the lens (a keratometer it really is) by observing the images of special parts reflected from their surfaces. The estimation of such images was not an original discovery by Javal, for, years previously, Young and others had devised instruments for the purpose, and Helmholtz more recently had perfected an instrument which Donders deemed to be "one of the greatest treasures for which we are indebted to his genius." Yet, today, we owe to Javal and Schiötz, his Norwegian collaborator in the laboratory of the Sorbonne, the simplified instrument with which we can rapidly study the cornea's curvature.

Their first perfected instrument was exhibited at the International Medical Congress, held in London, 1881. The ophthalmometer took a place among the approximate tests in the practical working out of ametropia. Its indications are definite and the ease and rapidity with which these may be obtained betokens its usefulness. The results which can be reached with scientific precision and accuracy, in the case of astigmatism in aphakic eyes, assure us of its distinct value. It has positive limitations in usefulness, however, for it does not give the refractive condition as a whole, nor furnish indication as to the existence of myopia or hyperopia; neverthe-

less, while giving with exactness the radii, in all meridians, of curvature of the cornea, it manifests the directions of the principal ones.

The history of the Javal ophthalmometer may be found in a volume, edited by Javal, entitled "*Mémoires d'ophtalmométrie*," containing a number of papers by many writers, European and American, including Theobald and Swan Burnett, who became ardent advocates of the use of the instrument.

We are indebted to Javal for the adoption of the metric system in the dioptric numeration of lenses, and the abandoning of the old inch measures. He suggested also gilded rims for the concave lenses and silver for the convex. He devised the star or fan for the estimation of astigmatism. He urged the increased utilization of cylindric lenses even in low degrees of error.

In 1885, at the end of an election campaign, by a sad irony of fate, in spite of skillful treatment, his right eye was blinded by glaucoma. In the succeeding years he suffered many transitory attacks in his left eye. In 1897, the excitement of the Dreyfus trial at Rennes precipitated the final attack. He was kept more or less under the influence of pilocarpine during 15 years of active work. In 1900 he went to England for treatment, under the direction of Priestley Smith. An iridectomy gave only temporary relief, and, during the succeeding five months, in spite of all efforts, the eye became blind. On his return to Paris, by his own desire, the cervical sympathetic was divided, but with no benefit to his sight.

This terrible affliction did not dampen his spirit. On the contrary, with philosophic fortitude he promptly set himself to study the means by which the lot of those who lost their sight during active adult years might be ameliorated. Javal early found, as did Helen Keller, that

"the greatest curse of the blind is not blindness, but idleness." After three years of experience he issued a little book which he called "Entre aveugles." It has been translated into many languages; the English version bears the title "The blind man's world"; my American edition, published in 1905, "On becoming blind." The author counsels the blind and their friends on such matters as "Replacing sight by other senses"; "Household and professional occupations"; "Marriage"; "Neatness, hygiene, health"; "Dwelling"; "Meals"; "Watches and clocks"; "Walking"; "Tandem tricycle"; "Travelling"; "Reading aloud"; "Handwriting and type-writing, including raised, or embossed Braille"; "Music"; "Games"; "Tobacco"; "Esperanto"; "The sixth sense"; and a chapter on the "Psychology of the blind."

The book is a fine instance of valuable work planned and carried out under a calamity great enough to overwhelm most individuals. In reading between the lines one is impressed by the sincerity of the afflicted gentle soul whose efforts to help others are but expressions of his determination to conquer his own helplessness. Friends returning from visits to France repeatedly told me of their having seen Dr. Javal on his tricycle wheeling through the streets of Paris; and, medical men of their conferences with him.

In 1894 Javal edited and prefaced an edition of the ophthalmologic works of Thomas Young which Tscherning had translated into French, published in Copenhagen.

During these latter years Javal was preparing another important work "Physiologie de la lecture et de l'écriture" which appeared in 1906. It describes the evolution of written and printed characters, including those of stenography, musical notation, and relief-writing for the blind. He discussed the principles on which letters should be

formed to afford the maximum legibility and he indicates how handwriting might be so faulty as to become "an offence to common sense." The first edition was exhausted in three months.

These works show how keen and how purposeful was Javal's interest in many things; "Esperanto," for instance, and "Spelling reform," and, always unceasingly, means for improving the condition of the blind.

Javal was a deeply religious man, maintaining the highest ideals in his daily life. Many honors were granted him; honors that indicate the appreciation of the world for his service to medicine and to ophthalmology. In 1885 he was elected to the "Académie de Médecine," and honorary member of the Ophthalmological Society of the United Kingdom of Great Britain, having been invited to deliver the Bowman Lecture in 1907. His health was such, however, that he could not undertake the journey. Death soon followed from the effects of gastric cancer, January 20, 1907.

My desire to tell of the life and works of Emile Javal rests on a long-held belief that he is preëminently the exemplar for the new-education of the sightless and the guide leading the blind onward in self-dependence. It would be natural for him, and for ourselves to expect him, to offer advice to practicing ophthalmologists, something of the means with which to lighten the misery of their unfortunate patients and others. The little book is packed with suggestions for ways to enable the adult blind to "live with the least possible evil with their infirmity." Children, as we all know, are reported on early, and are sent to schools for their special instructions, and are taught all the arts and maneuvers enabling them to enter life with remarkable independence.

Javal's avowed purpose was to write for the family of the blind, offering to

them helps attainable at the smallest cost, with which they themselves can lighten their burden in living with the blind one. The chief burden of the blind, as he knew and as we, too, know, is their forced dependence on others.

He begs us "to resist" what he calls "the barbaric tendency" to leave our patients with the hope of recovery, whose course toward blindness is certain, that by injections of one or more kinds of drugs, electrical currents, or useless internal medicine, their condition can be relieved. To give consolation by a placebo treatment to an incurable is to prevent him from arranging his life in anticipation of the fatal outcome. It is more humane to prepare them, little by little, for their fate. He, accordingly, wishing that there might be done for others what he would have liked to have had done for himself, sent forth this little book with the hope that it might serve to render easier some ill-fortune like his own and thereby give to himself the special consolation of having helped others.

The appliances and other helps which he recommended, and all that have been devised since his time, can be obtained through the Blind Societies in any city in the country. No person is too old to learn to use them; the struggles of the teachers are concerned almost entirely in enforcing the will of the pupils to accept instruction and to carry on after the lessons have been accomplished.

Out of my great admiration for Javal, my desire has been to make a special appeal to ophthalmologists to consider the future of those whose sight is irrevocably falling into helpless blindness. Just here there occurs to me the knowl-

edge that two ladies, well beyond 60 years of age, suffering from high-grade myopia—one with well-preserved backgrounds—but who has had repeated extravasations—the other with ragged backgrounds and cataractous lenses, each has in the past two years become so skillful in typewriting as to be able to carry on correspondence with their friends and conduct their daily business notes. A gentleman, when forced to reside at a great distance from civilization, took up beekeeping. Later, when I extracted his lenses, so brilliant became his sight that he, at times, regretted that he had had them extracted—so simple and easy had life become, he was no longer his own hero.

For several years I have been one of the Pennsylvania Home Teaching Society for the Blind and have the honor to be the President of the Board which manages the affairs arranged solely for the benefit of the hundreds of adult pupils to whom annually thousands of visits are made by a staff of competent, though entirely blind teachers.

My allusion to these facts arises from the likelihood, and indeed the probability, of a great increase in the number of the blind following the present worldwide cataclysm—both civilian, and through "grim-visaged War."

In the Archives of Ophthalmology for April, 1939, in commemoration of the centenary of Javal's birth, James Leber-son published a sympathetic tribute to the master. In that you will find what I have wished I might have had the time to tell of his personality, to add to the brief, matter-of-fact account I have given.

ENDOPHTHALMITIS PHACO-ANAPHYLACTICA*

RICHARD G. SCOBEE, M.D., AND HOWARD C. SLAUGHTER, M.D.

Saint Louis

It was in 1934 that Burky¹ first reported his ingenious method for the production of experimental endophthalmitis phaco-anaphylactica in rabbits. In his report he also gave a brief but complete summary of the work and ideas on the subject up to that time. There is no need for its repetition here. To the best of our knowledge, his work has not been confirmed in the literature, and hence this paper in confirmation.

Burky² had previously noted that rabbits given intracutaneous injections of staphylococcus toxin developed not only an antitoxin for the toxin but also a hypersensitive state to the beef broth in which the toxin was produced. He reasoned that if such a poor antigen as beef broth could be made active by the intermediary action of staphylococcus toxin, then this same toxin might have a similar action on lens substance.

The experiments which he then devised bore out his idea, the results confirming the hypothesis of Verhoeff and Lemoine³ concerning the allergic nature of endophthalmitis phaco-anaphylactica. He demonstrated that such an allergic state could be attained through the intermediary action of bacterial toxin.

It is not necessary to describe his technique here in detail; those interested should read his original paper.¹ It is our purpose merely to confirm Burky's work, the confirmation being the first step in a series of experiments having to do with the possible relation between endophthalmitis phaco-anaphylactica and sympathetic ophthalmia. DeVeer⁴ (1940) wrote

an excellent article on this subject, speculating upon a possible relationship between the two entities and citing several case histories in support of his speculations; no experimental work was done, however.

EXPERIMENTAL

According to the method of Burky, both a lens extract (of beef eyes) and a lens-broth toxin were prepared, an HA strain of *Staphylococcus* being used for the latter. Seven rabbits were then prepared for intracutaneous injection by depilation with barium sulfide. Two rabbits were given 0.5-c.c. intravenous injections of the lens extract each week. The others received at weekly intervals 0.1 c.c. of lens-broth toxin in one cutaneous area and 0.1 c.c. of lens extract in another cutaneous area. Reactions were recorded by measuring the maximum diameter of erythema, swelling, and necrosis in millimeters.

The first injections were followed by erythema and swelling, which appeared in from 24 to 48 hours. It is interesting to note that, in contrast to the observations of Burky, the cutaneous reactions of our group of rabbits seemed to decrease rather than increase with each subsequent injection, yet the final outcome was the same; that is, a clinical and histologic picture of endophthalmitis phaco-anaphylactica. Also in our series, necrosis was absent or minimal. These findings were the same both for the lens extract and the lens-broth toxin. Burky found that the majority of his rabbits attained their maximum sensitivity (cutaneous) following the fourth injection. Because of the lack of any marked skin reaction indicative of a developing cutaneous sensitivity, our

* From the Washington University School of Medicine, Department of Ophthalmology, Oscar Johnson Institute.

series was carried to seven injections in an unsuccessful attempt to demonstrate this same cutaneous sensitivity. A small erythematous area measuring from 0.5 to 1.0 cm. would occasionally mark an injection site 24 or 48 hours later. There were numerous occasions on which not even this small skin reaction could be noted.

and remained there when the syringe method was used; another factor was, perhaps, that of internal swelling of the lens material produced by the injected aqueous, forcing apart the lamellae.

The eyes were enucleated at varying times following this experimental trauma. Two eyes had to be removed on the fourth day to prevent their rupture, and one

Figs. 1 and 2 (Scobee and Slaughter). Endophthalmitis phaco-anaphylactica. Fig. 1, Low-power section of entire globe showing reaction of endophthalmitis phaco-anaphylactica. Fig. 2, Higher-power view of section of figure 1 as indicated by lines. The lens substance shows monocytic invasion, and dissolution can be seen at the left. The heavy, dark-staining infiltrate at the right is the surface of the ciliary body. A zone of relatively clear cortex is between the two infiltrative zones.

At the completion of this series of sensitizing injections, the right eye of each of the rabbits was needled with a Ziegler knife-needle, a crucial incision being made in the lens. Two days later, the left eyes were needled according to Burky's method of aspirating aqueous in a hypodermic syringe and then injecting the aqueous thus obtained deep into the center of the crystalline lens. It was noted that although similar clinical and histologic pictures developed in both eyes of each sensitized rabbit, the reaction was definitely more marked in the left eyes (traumatized by Burky's method). This might be expected, since aqueous was brought into contact with lens material

ruptured during its removal. The same thing happened in Burky's series. The remaining eyes were enucleated on the tenth day, when clinically all showed an endophthalmitic reaction of varying degrees of severity. There was suspicion of secondary infection on clinical grounds in two of the eyes, and this was confirmed histologically by the predominantly polymorphonuclear character of the infiltrate in them. Eyes from the control rabbit showed only a normal response to the trauma of needling. Rabbits 9 and 11 were those which received the intravenous injections of lens extract and they showed practically no reaction other than that due to the trauma of the needling.

Dr. T. E. Sanders was kind enough to study the group of eyes pathologically, and his report was as follows:

"The reactions in these eyes varied from very mild to extremely severe. In all cases, the reaction was chiefly localized in the anterior segment. In the mild cases, there was no particular inflammatory reaction. There was a wound of the an-

terior lens capsule with varying degrees of degenerative cataractous formation. This process usually extended around to the posterior capsule. There were varying degrees of attempts at healing in the anterior capsular wounds by a fibroblastic reaction. Inside the posterior capsule, a peculiar cellular ingrowth formed almost a posterior epithelial layer; this apparently arose from the region of the equator. The posterior subcapsular cells were present in the eyes of rabbits receiving the intravenous injections as well as those which had the intracutaneous ones. There

was a homogeneous eosinophilic substance in the anterior chamber.

"The eyes showed a chronic inflammatory reaction, chiefly in the area of the lens trauma. This consisted of a heavy infiltration of chronic inflammatory cells in the area of liquefied lens and extended out somewhat into the more intact lens substance. There were relatively dense

TABLE 1
SUMMARY OF OCULAR REACTIONS

Rabbit No.	Injections before Needling	Cutaneous Sensitivity to Lens Extract at Needling	Ocular Reactions		Day of Enucleation
			Clinical	Histological	
Group I. Lens-broth toxin and lens extract intracutaneous injections					
1	7	Waning	Positive	Positive	10th
2	7	Positive	Positive	Positive	10th
3	7	Positive	Doubtful	Doubtful	10th
5	7	Waning	Positive	Positive O.S. Secondary infect. in O.D.	10th
6	7	Waning	Positive	Positive	4th
7	7	Positive	Positive	Positive O.D. Secondary infect. in O.S.	10th
8	7	Waning	Positive	Positive	4th
Group II. Lens extract injected intravenously					
9	7	Negative	Trauma	Negative	10th
11	7	Negative	Trauma	Negative	10th
Group III. Normal control rabbit					
10	None	None	Trauma	Negative O.S. Secondary infect. in O.D.	10th

terior lens capsule with varying degrees of degenerative cataractous formation. This process usually extended around to the posterior capsule. There were varying degrees of attempts at healing in the anterior capsular wounds by a fibroblastic reaction. Inside the posterior capsule, a peculiar cellular ingrowth formed almost a posterior epithelial layer; this apparently arose from the region of the equator. The posterior subcapsular cells were present in the eyes of rabbits receiving the intravenous injections as well as those which had the intracutaneous ones. There

posterior synechiae but relatively little infiltration into the iris tissue in the milder cases. The infiltrate was predominantly monocyctic, with a few lymphocytes and polymorphonuclear cells. There was no evidence of necrosis; varying degrees of vasodilation of the iris vessels were noted. A moderate number of monocytes were seen on the endothelium of the cornea, on the surface of the ciliary body, and on the nerve head. This distribution was essentially that of chronic endophthalmitis.

"In the more severely involved eyes, a marked keratitis was present near the

limbus which included all the layers of the cornea and seemed to have no relation to the site of corneal penetration from the needling. On one side, this keratitic area was so thin that early ciliary staphylomata were seen. Over the surface of the retina in the more severely inflamed eyes could be seen monocytic cells. In the secondarily infected eyes, the polymorphonuclear cell was quite prominent in the infiltrate.

"In the group of eyes not secondarily infected, the pathologic picture was one of endophthalmitis, with predominantly a monocytic infiltration, hence a 'chronic endophthalmitis.'"

COMMENT

Friedenwald⁵ has stated that the character of the cellular infiltrate is of some value in distinguishing the findings in the allergic animals from those in accidentally infected control animals. In the latter, the cells are predominantly polymorphonu-

clear, whereas in the allergic animals, they are predominantly monocytic.

SUMMARY

Herewith is presented confirmation of Burky's work of 1934; namely, that cutaneous sensitivity to lens substance in rabbits can be induced by repeated and coincident injections of staphylococcus toxin and lens substance. When the eyes of such sensitive rabbits are needled, a clinical and histologic picture develops that resembles endophthalmitis phaco-anaphylactica in man. Our series did not show the cutaneous sensitivity which Burky mentioned, yet end results were the same. We report this confirmation of Burky's work as the first step in a series of experiments having to do with endophthalmitis phaco-anaphylactica and sympathetic ophthalmia.

VISUAL ACUITY AT LOW BRIGHTNESS-LEVELS*

MATTHEW LUCKIESH, D.Sc., AND A. H. TAYLOR

Cleveland

Visual acuity, or the ability to distinguish fine detail, is often of little importance at very low brightness-levels. Contrast sensitivity, or the ability to distinguish small differences in brightness, is commonly of great importance at low brightness-levels such as are encountered outdoors at night. For example, visual acuity has been greatly overemphasized as compared to contrast sensitivity in the testing of automobile drivers for seeing at night. Also there are many problems of seeing in war activities which involve concealment, dark adaptation, and very low brightness-levels at night under moonlight, starlight, and even dark, overcast skies. Lookouts on ships, pilots and observers in airplanes, and drivers of trucks might well be tested for contrast sensitivity. Researches by the authors have revealed a wide diversity in this function even among subjects who have the same visual-acuity or visual-efficiency ratings by the usual methods.¹

On the other hand, there are some activities in which it is necessary to distinguish fine details under the least amount of light, or lowest brightness, that is practicable. Scales of instruments, maps, charts, and other details must be read with accuracy and as easily as possible under blackout or dimout conditions. In various researches² in connection with problems of seeing in wartime, the authors have had to study the effects of illuminants of various spectral characters upon visual acuity. Subjects vary greatly in their ability to see at low brightness-levels, but the data presented herewith were obtained by subjects who appear

to be fairly representative. However, the quantitative results are less important than the decisive differences among illuminants. For this reason the results are presented in diagrams rather than in tables.

In figure 1 are shown typical results obtained with the A.M.A. test chart for seven different illuminants representing a wide range in spectral character. Under each illuminant the subjects were adapted for 30 minutes at approximately the brightness-level at which the largest letters could be distinguished at the test distance of 20 feet. The chart was located in the center of a circular, white field which subtended an angle of 20 degrees. This surrounding field and the test chart were illuminated by the same illuminant. After determining the test line which could barely be read, the brightness of the white background of the test chart was determined by someone other than the subject. Then the background brightness was increased and after adaptation for a standard length of time, about five minutes, the subjects again determined the test line which could barely be read. This procedure was continued for all the lines of the test chart. In all cases foveal vision was used, although in some cases apparently a slightly high visual acuity was obtainable by slightly averted vision.

On figure 1 the illuminants designated by the letter *F* are regular fluorescent lamps. The tungsten-filament lamp was a regular 150-watt lamp and the photographic red lamp was a 40-watt tungsten filament in a red-glass bulb.

It is obvious that as the illuminants progress in integral color from blue to red, there is a progressive decrease in the

Fig. 1 (Luckiesh and Taylor). Minimum brightnesses obtained with different colored fluorescent (F) lamps, a regular 150-watt tungsten-filament lamp, and a photographic red lamp, at which various lines of letters of the A.M.A. test chart can barely be read.

Fig. 2 (Luckiesh and Taylor). Background brightness required for slightly above threshold "readability" of type sizes with (A) tungsten-filament lamp at 105 volts (color-temperature approximately 3,050 degrees K), (B) the same lamp at 40 volts, and (C) the same lamp at 105 volts with Corning HR Signal Red no. 243 filter.

minimum brightness of the background of the test chart at which a given test line can be read. In other words, red light is more effective for a given brightness than the other illuminants. This is a very important matter in many wartime activities where it is necessary to see details with a minimum of brightness.

These data afford a basis for many recommendations. For example, suppose letters, numbers, or other details subtend a visual angle of 20 minutes, corresponding to line 9 on the A.M.A. test chart. The minimum background brightness for such details of maximal contrast (black on a white background) should be about 0.0035 footlambert for tungsten-filament light and about 0.00014 footlambert for red light from a photographic red lamp. This is an enormous difference, for the former brightness is 25 times the latter. Such great differences are of much practical value where concealment, visibility, and the maintaining of a high state of dark adaptation are involved. Of course, to insure certainty of seeing, somewhat higher brightness values should be used.

For those used to thinking in terms of foot-candles or in measuring foot-candles, a definition of the foot-lambert may be helpful. If a perfectly diffusing white surface had a reflection-factor of 100 percent, a foot-candle of illumination produces a foot-lambert of brightness. The white surfaces used reflected about 83 percent of the incident light and therefore had a brightness of 0.83 foot-lambert for each foot-candle of illumination. Therefore, if the foot-lambert values are multiplied by a factor of 1.2, they are converted into approximate foot-candle values.¹

In figure 2 are shown the results obtained for three illuminants for reading-matter printed with black ink on white

paper. The type sizes ranged approximately from 6-point to 20-point. Curve A is a plot of results obtained for a 115-volt tungsten-filament lamp operated at 105 volts, the color-temperature of the light being 3,050 degrees K. Curve B is for the same lamp operating at 40 volts. Curve C is for a fairly saturated red light.

In figure 2 are shown the background brightnesses for the three illuminants which are respectively necessary in order to read with certainty type of a given size when printed with black ink on white paper. Here again the great advantage of red light is revealed; that is, when details are to be distinguished with a minimum brightness.

In obtaining the data plotted in figure 2, the subject was seated at a table and the reading matter was inclined at approximately 45 degrees. The light was confined to the reading matter by means of a projector and iris diaphragm. The subjects were adapted for 30 minutes to the brightness of the reading matter, the brightness being just sufficient so that the printed matter was just below the threshold of "readability" of the largest type. After adaptation the brightness necessary for reading without uncertainty was determined. Then the next smaller type was placed in position. After a standard rest period the procedure was repeated.

The work of the authors has shown in other ways² the great advantage of red light in a variety of problems of seeing in wartime—blackouts, dimouts, instrument dials, charts, orders—where concealment is vital³ and where dark adaptation must be maintained. The results have many other applications in indicating the visual size of details necessary if they are to be distinguished under very low brightness-levels.

ORTHOPTICS FOR THE INFANT SQUINTER, ONE TO FOUR YEARS OLD*

EDITH V. ROTH
Milwaukee, Wisconsin

I have been asked to take up the various aspects of our present orthoptic treatment of the infant squinter at the Milwaukee Children's Hospital. However, orthoptic treatment cannot possibly be divorced from ophthalmologic treatment, especially in the infant. Therefore, I shall discuss the ophthalmologic treatment of strabismus in children under four. I only hope that this will not seem too presumptuous on the part of an orthoptic technician. Any opinions expressed on points other than those applying strictly to orthoptics are, of course, the opinions of the ophthalmologists on the Hospital staff.

At the Milwaukee Children's Hospital, an immediate examination, even at six months of age, is considered advisable for several reasons: (1) There are the occasional cases of +8 diopters or more of hyperopia. (2) There are the many cases of pseudostrabismus due to a wide epicanthus, in which the ophthalmologist can assure the parents that, although there is a definite illusion of strabismus, none is actually present. (3) There are the cases in which a true strabismus is found,

due to some organic anomaly or disease.

In all cases of squint that show high refractive errors under a 0.5 percent atropine cycloplegia, glasses are routinely prescribed. In this regard, it is always wise to keep in mind that even a baby will wear glasses if he truly needs them. However, nothing in the world will make a baby keep them on if he does not need them.

When the refraction has been done, the ophthalmologist generally turns the infant squinter over to the orthoptic technician with the familiar words, "Would you like to *try* to get a vision on this child?" With the average child of two to four years of age, a vision usually can be obtained, if not by one method or on that day, by another method, perhaps, or on another day. The illiterate E or "piggy" game as we call it, the Kindergarten chart, the Berens chart, the Landolt broken-ring test, or graded blocks can be used. I am told that the Bailey visual-acuity test is often helpful with a child who has difficulty in understanding what is expected on some of the other tests. In this test, the child is asked to pick from a tray at his side miniature models which match the object-pictures on the chart. Of course, making a game out of any method

*From the Milwaukee Children's Hospital. Read at the second annual meeting of the American Association of Orthoptic Technicians, in Chicago, October 12, 1942.

will get results much quicker than expecting the child to sit up and pay attention to a chart on the wall, which many times will probably look like a lot of Greek hieroglyphics. In any child of this age, obtaining a satisfactory visual finding is a challenge and, as it constitutes the first introduction to the little patient, it requires all the resourcefulness at one's command.

When this has been done, the little squinter is generally turned over to the orthoptic technician for a diagnostic series of five or six visits. In the event that a visual acuity has not been obtained, the *fixating* eye, in a case of monocular squint, or the preferred eye, in an alternating squint, is always easily determined, except in a few cases of alternating squint in which there is no marked preference of either eye. At this time, the parent is instructed as to the form of constant occlusion to be used following the diagnostic series, if it is known that occlusion is indicated. In very simple language the parent is told that occlusion must be used in the better or *fixating* eye in order to prevent an amblyopia ex anopsia from developing or to improve the vision in an eye already amblyopic. When occlusion is later begun, we usually, in the beginning, use complete occlusion—a patch over the eye if no glasses are being worn or a Stark occluder attached to the glasses if the latter have been found necessary. Both are cut out of waterproof adhesive tape and shaped to the individual face or pair of glasses. When the vision is found to be 20/70 or better, a less complete, but still constant form of occlusion may be substituted by pasting an opaque paper or gummed, translucent mending tape to the lens of the better eye. The possibility of the child's peeking then must be carefully watched. If the complete occlusion on the face of the child who needs no glasses is found too harsh a treatment to be continued indefinitely, a pair of plano

lenses may be prescribed for the duration. Of course, there is always a question as to whether or not the child will keep these on. Other forms of occlusion can then be easily devised by the ingenious parent, such as a soft wide bandeau or a net bonnet, with the patch attached.

Not only is this monocular occlusion considered important for the prevention or improvement of amblyopia but also for the prevention of secondary contractures of muscles, by giving the patient a sufficient amount of monocular exercise. In the case of alternating squinters, an alternate occlusion of first one eye and then the other is usually suggested in order to prevent the development of an abnormal retinal correspondence. When binocular vision is found to be possible, a fogging of the lens of the stronger eye is sometimes suggested. This fogging of the lens may be accomplished in numerous ways, such as by the use of Scotch cellulose tape, a stippling of colorless nail polish, a clip-on smoked glass, or a red kodaloid filter. All of these forms of partial occlusion are of course advised only for infant squinters who have a normal retinal correspondence of long standing.

When the vision, fixation, and the necessity of occlusion have been determined, at least an estimate of the angle of squint is made. At three to four years of age this is usually possible for distance and near vision with the use of a cover test; then, at the same time, monocular and binocular rotations are generally attempted. With a baby under three it is possible only to estimate the angle approximately by the Hirschberg method and to determine a marked paresis. To be sure, any testing attempted in the beginning must be in the nature of a game and in the spirit of play.

On the second visit, a near point of convergence with a colored pinhead or a light is easily elicited, and monocular and binocular rotations again attempted to

ascertain any limitation of motion or overshooting in any direction of gaze. The angle of deviation in the primary position for distance and near is again checked.

The next step is to evaluate the amount of binocular vision the child has in his everyday life. Here we are forced to digress from the routine testing and find out, before going further, if the child knows colors and can count. Needless to say, the Worth dot test, which is the simplest method of estimating the patient's binocular vision, is possible only on a child of three or older. But since it is basically a subjective test, we must determine how much we are going to be able to rely on the child's answers before attempting any actual testing. There are many children who will recognize red and possibly green in a familiar article and yet not be able to recognize it in the Worth four-dot test. We find it helpful to practice naming the colors with colored blocks, marbles, crayons, or even gum candies, before showing any colored lights, as we then know immediately if the colors can be recognized and named correctly. We also find it helpful to practice counting before doing any actual testing. To be sure, this all takes valuable time, but it is always time saved in the end.

On the second or third visit we usually attempt to obtain the measurement of squint and the kind of retinal correspondence on the major amblyoscope. Needless to say, this is not always possible in the case of a child under three years. With such fascinating targets as the lion and the cage, the butterfly and the net, the spider and web, or the bird and cage, we let the child show us where he puts them together, and then quickly flash to determine if the simultaneous macular perception is at his objective angle. If we stimulate the child, in the spirit of fun, to show us how good he is, we can usually determine, in repeated attempts, if he is

actually telling us what he sees or merely attempting to please. In the beginning, we generally find the child eager enough, and yet not too much aware of what he is supposed to see, to obtain the correct answers without much checking on our part. Of course, our flashing to determine the type of correspondence must be quick, as the child's concentration at this age is always poor, despite his eagerness and interest. No findings can be relied upon at this time unless they are corroborated on repeated attempts.

All of our tests are repeated on successive visits until we feel that we are able to give an accurate report of our findings of the visual acuity, fixation, degree of angle, type of correspondence, and measurement of fusion and stereopsis. Even the latter measurement is quite possible if the child's correspondence is normal and his fusion is good. In this event, it is possible that some fusion training at periodic visits may be prescribed to stabilize the present fusion and perhaps acquire some amplitude. However, this is rarely the case, for the average infant squinter at the Milwaukee Children's Hospital is usually advised, after the diagnostic series, to return only for bimonthly check-up visits until he has reached an age at which he can accept concentrated orthoptic treatments. Any actual training given at this time is mainly to help the child to become accustomed to the clinic and the technicians and to determine the type of occlusion, if the latter has been found necessary. On these visits, when the vision, fixation, angle of deviation, and fusion on the major amblyoscope have been checked, there is often time to include numerous other orthoptic activities such as amblyopic exercises or, if the correspondence is normal, cheirosopic work with mosaic patterns, blocks, or small models. Then, when the mother has become familiar with the many monocular

exercises for the infant squinter, she may be given work to supervise at home. These exercises may include coloring outlined pictures, tracing stencils, fitting picture-puzzle or construction blocks, stringing beads, cutting out pictures of all kinds such as paper dolls, or sewing dotted picture-cards. The last two activities of course require dull-pointed scissors with a rounded top and needles with ferruled ends. All of these exercises should be supervised to a certain extent but still allowed to remain play activities of the child.

It must be admitted that all of us are tempted constantly to try active treatment on these little squinters, who are always ready for our games, but we all know that usually even the attempt is a mistake.

These infant bodies and minds are quite naturally not capable of anything but play in a very active form, and these baby eyes cannot be taught to work together in any form of play. The awakening of latent fusion requires much intense concentration, which is often a real task for the adult. To attempt such teaching with a child under four is to take the chance of creating a distaste in the infant's mind for all orthoptic exercises—a distaste that will always be remembered. Before taking such a chance, in any case, should we not ask ourselves if it is really worthwhile and will it not be better to let the infant wait for straight eyes until he is ready to coöperate without endangering his body and mind?

721 North Seventeenth Street.

THE USE OF PRISMS IN ORTHOPTICS*

CLARA BURRI, PH.D.
Chicago

I am always impressed by those who categorically can enumerate the pros and cons of a given method or procedure in orthoptics; since to me any orthoptic instrument, or method of measurement or training, must be adapted to the specific case. The goal, however, is always the same; namely, the reëducation of a disturbed visio-motor-fusion mechanism. Every patient who comes to me I look upon as an individual with a distinct problem in the use of binocular vision, and my aim is to help that individual to solve his problem, which means to teach him how to attain normal and comfortable binocular vision; or, in some cases, to attain parallelism of the visual axes if possible. I never treat or train just eyes. I always train a person. With this point of view my methods of training are very flexible and adjusted to each particular individual. Not that I do not have some general or fundamental methods and tools. I do, but I may vary them, or use them in various combinations, according to the specific problem.

In each and every case I ask myself, first of all, which method or combination of methods will bring my patient most quickly to his goal; and, of course, as each personality differs the methods of approach must vary accordingly. Since I never train a squint or a phoria or a convergence insufficiency or a divergence excess, but rather, a person with a visual problem who is to be reëducated to achieve normal binocular vision, the methods of

training must always be consistent with existing laws of pedagogy. Thus the essential thing is to study each patient, to analyze the problem as it applies to him, and then to devise the system of procedures most likely to attain good results for that individual. With this point of view the methods of training may become as variable as are subjects or patients, and what may bring results in one case may give little success in another.

Thus when I was asked to prepare a paper on the use of prisms in orthoptics my first reaction was: Why not cover the whole subject of orthoptics, since prisms are used in one way or another throughout most of the field? However, this paper presents an attempt at systematizing the use of prisms and at categorizing some situations in orthoptics in which prisms are used to particular advantage. In order to do so, it is essential, perhaps, to divide the subject into: (1) the use of prisms for making diagnosis and measurements; and (2), the use of prisms for training and treatment, when these are continuously worn by the patient.

Prisms in measurements. For diagnosing and measuring muscle anomalies prisms have become one of our primary tools. An ocular-muscle examination without the use of prisms is hardly conceivable. The cover test is the quickest and one of the most accurate of all tests with which to measure deviations, and it should be in continuous use for every case and at almost every visit. The cover test not only gives accurate and quantitative measurements, but it also furnishes a quick check on the results obtained by other tests, and a quick review of a given case preliminary to each training period. The

*From the Department of Ophthalmology, Northwestern University Medical School, Northwestern University. Read at the second annual meeting of the American Association of Orthoptic Technicians, in Chicago, October 12, 1942.

cover test, carried out with the aid of either loose hand prisms or any standard prism bar or rotary prism, is the one single tool which may be considered essential for the routine examination. The test should be carried out in the primary and the six cardinal positions.

Again prisms are used in the Maddox rod test in which that amount of prism is found which gives the patient superposition of the light and Maddox streak. The numerical reading on the prism is the quantitative measure of the existing deviation, expressed in terms of prism diopters. This may be eso-, exo-, or hyperphoric; or it may be eso-, exo-, or hypertropic.

A similar test for which prisms are necessary is the diplopia test, which may be used with a red and green light or the letters "ONE." In this test, as in all others in which a deviation is measured, prisms base out are used to bring about convergence until the two images coincide, whereas in cases of divergence, prisms base in are used. These tests are particularly well adapted for testing hyperphorias, when the prisms must be placed either base down or up, depending on the case. The numerical reading of that strength of prism which gives superposition or alignment of the two images denotes the degree of the deviation; provided correspondence is normal. If fusion of the two images occurs at the expense of a false correspondence, there will be movement of the eye when covered. If the two maculas are used there will be no movement. Since this paper deals with the use of prisms as tools in orthoptics and the procedure in making a particular test is described only by way of exemplifying the use of prisms, normal correspondence should always be assumed. It must be borne in mind that abnormal correspondence often changes the procedure or, at any rate, the evaluation of the findings.

Finally, prisms are used to measure ductions. Prisms of increasing strength, either base out or base in, are placed before the patient's eyes while he is observing a small light either at 20 feet or at the reading distance. The degree of prism that induces diplopia represents the duction strength; base out measures adduction and base in abduction, base up infraduction and base down supraduction.

In cases of very high deviations the use of additional prisms may sometimes be necessary in some of the amblyoscopes and the rotoscope, but the measurements obtained in this way are usually not very reliable, because it becomes difficult to fixate with both eyes owing to the mode of construction of the instrument.

Prisms for training may be used in various ways. They become a useful tool when employed in loose-prism exercises or they may be used in connection with some instrument. If the angle of squint is over 10 degrees of convergence or divergence, prisms are frequently helpful in such instruments as the myoscope, cheiroscope, and the stereoscope. For example, in using the myoscope, the patient may be given red and green spectacles and then be made to try to fuse the two colored images into one. If the angle of squint is so large that the eyes cannot fuse these images, prisms are placed in the lens holders. These prisms must be strong enough so that the images come together within the range of fusion. When fusion amplitude increases, the prisms may be made weaker.

When the cheiroscope is used, prisms up to the strength of the squint must be placed over the lenses. The child should never be allowed to work without prisms of the proper strength; otherwise he will not be able to fuse, and will only practice alternating fixation.

Variable prisms are also useful in connection with the stereoscope, which aids in

developing amplitude of fusion; and to give abduction and adduction exercises from home training. However, before any of these instruments are used care must be taken that the patient does not suppress or alternate, and especially that normal correspondence has been well established.

In cases of squint prism exercises with loose prisms are of doubtful value. Perhaps with very intelligent and coöperative patients loose prism exercises may be prescribed for home exercises; especially in postoperative cases in which only small amounts of squint remain and in which fusion and good fusion amplitude were well developed before the operation. In this case the prism should be used base out for convergent squint, and base in for divergent squint, the strength being such as to allow the patient to fuse the two images. The prism should be held in front of one eye, and the strength gradually decreased. A prism bar of graduated prisms is useful for this type of exercise, and the training should be done at various distances from the eyes.

Even if exercises with loose prisms are of doubtful value in cases of large deviations, they are most useful in dealing with phorias, especially exophorias. It is essential that the kind of phoria be carefully diagnosed and the individual's ability to cope with that phoria. This necessitates careful measurements of the phoria and the ductions, and for these measurements prisms and a Maddox rod may be employed to great advantage. The measurements are made in the manner aforedescribed. The maximum strength of prism which the patient can overcome is the measure of his duction power. According to Dr. Berens, the normal ratio of abduction to adduction is considered to be one to three. But it is not only important to ascertain the ratio and the breaking point and that of recovery, but also to consider the relationship of the size of the duction

to that of the phoria. What is frequently considered a fair average of adduction power for orthophoric eyes may be completely insufficient when a phoria is present, and by increasing the adduction reserve comfortable vision may be achieved.

For esophoria and abduction weakness prism exercises alone are frequently not very effective. However, in making the attempt, prisms base in are placed before each eye and their strength gradually increased until the maximum strength is reached. Better results will be obtained in prism training with stereoscopic exercises on one of the stereoscopes, or the rotoscope, or one of the major amblyoscopes. When the ordinary stereoscope is used it must be equipped with spring clips for the prisms. These may be increased one or two diopters at a time. This exercise is of benefit in cases wherein the phoria is small and there exists a weak abduction. When there is a fair sized esophoria that is greater for near than for distance, and greater without than with the correction (if this is hyperopic), good results may be obtained with prism and stereoptic exercises after the physician has prescribed full correction. Still better results are obtained if the patient uses some homatropine at night. This last procedure usually helps if the phoria is due to accommodative spasms.

But it is in cases of exophoria and convergence insufficiency that prism exercises may be used with best results. In this exercise one increases the ability to converge by placing the prisms base out in increasing strength. The patient begins with prisms of moderate strength, small enough so that he is well able to overcome them. The prism strength is gradually increased to a maximum degree. The exercise should be performed daily for 10 to 15 minutes. In many cases the patient will learn to overcome the effect of from 50 to 80 prism diopters. Of course fre-

quently these exercises should be supplemented by exercises on one of the major amblyoscopes, the rotoscope, or other major training instruments. These directions are not meant to imply that the exercises described are necessarily the best, nor that they should always be used, but merely indicate the various possibilities of using prisms for orthoptic training. Prism exercises frequently have no effect on the exophoria. However, since they increase the convergence and adduction power and reserve, they increase the individual's ability to cope with his phoria so that he becomes able to read and do other near work with greater comfort.

In order to determine the proper treatment for a given condition, a careful analysis of a patient's muscle imbalance must be made. One should distinguish between different types of exophorias. There is the accommodative type that is found in myopia, and essential exophoria that is apparently unrelated to refractive errors. The latter normally occurs in patients with hyperopia, and quite often the refractive error is very small. Here an insufficient convergence is present or one that is weak. Exophoria is present in presbyopic eyes, in which the accommodation becomes less as the lens becomes sclerosed. Furthermore, the use of bifocals diminishes the response required from the ciliary muscles, which diminution is followed by a corresponding relaxation of convergence. The choice of the treatment should be determined by all these factors, and after the physician has ascertained the refraction and has cleared up any problems of general health. If exercises are prescribed, loose prisms or prisms in connection with some training instrument may be used, but these should not be considered the most satisfactory methods.

In cases of vertical deviations prism training is not so satisfactory, perhaps because the average vertical muscle balance

is stable, varying but little up or down. Three or four degrees is about the limit of one's supraduction or infraduction ability. Since the flexibility in vertical balance is so slight, training with prisms will accomplish but little. However, occasionally a patient is found who benefits from exercises with vertical prisms, carried out on the rotoscope or some other training instrument. Two cases in particular may be cited. In the one there was a right hyperphoria of four prism diopters. Incorporated in her glasses the patient wore prisms that corrected the hyperphoria. When wearing those glasses she had frequent diplopia and headaches. However, after receiving fusion and duction exercises on the rotoscope, during which time the strength of the correcting prisms was gradually decreased at each session, she was able to dispense with the prisms except for near work, and diplopia occurred only when she was tired.

The other patient, a dental student with an old paralysis, gradually decreased a varying left hypertropia of 8 to 13 prism diopters to a constant hyperphoria of 3 diopters. He took exercises for more than six months, and now is wearing in his correction 2 prism diopters base down before the left eye and 1 prism diopter base up before the right eye. Of course it may be suggested that his hypertropia decreased because of a gradual and natural disappearance of the paralysis. This may be true, but this condition existed for over five years previous to the treatment. Surgery had been advised but the patient preferred to try the exercises first.

Prisms for constant wear. Some authorities have advocated the use of prisms for squint. The principle is to place before the eyes a prism of such strength that rays of light entering the eyes are diverted so that diplopia is avoided, or, theoretically, so that the rays fall on the maculas and fusion is forced even though

convergence is present. These prisms are worn in addition to the ordinary glasses, usually in the form of slip-overs. The theory is that the prisms produce a desire to fuse and as fusion develops more and more strength of the prisms is continually decreased until the patient can fuse with the eyes in the primary position.

There are several arguments against such a use of prisms in cases of convergent squint. First, according to the laws of learning, we cannot assume that a patient would learn fusion merely by the presence of prisms which divert the rays of light on the two maculas. If fusion could take place so easily many would probably have never developed a squint in the first place. Furthermore, if abnormal correspondence were present, that visual habit would be more recent and stronger than macular vision. According to the laws of learning we may assume that the eyes would tend to respond in the way most strongly fixed. That this actually happens is clear when we consider how difficult it sometimes is to break up abnormal correspondence. Also in cases where surgery was performed in the absence of orthoptic training either before or after the operation, the eyes frequently revert to the old position. Learning to see binocularly follows the same laws as any other type of learning, and in all learning formal practice is necessary. Psychologists have demonstrated many times that accidental learning is poor. According to this we may well doubt that the mere providing of the correct stimulus—namely, light diverted onto the maculas of both eyes—will be able to establish the correct habit. It requires active and controlled practice. There must be conscious practice in using the maculas together. Another argument that may be presented against the constant wear of prisms is that such prisms usually induce extreme discomfort. If the deviation is great the

weight of such glasses is considerable. Also dispersion of light frequently causes asthenopia and other symptoms of discomfort. Furthermore, it is important that the patient look through the optical center of his glasses, and when prisms are used the prismatic effect may easily displace that center when the glasses are not exactly centered, or when careless handling bends the frames.

Some ophthalmologists seem to prescribe prisms for constant wear for all types of phorias, particularly in exophorias and convergence insufficiency. In these cases prisms base in are ground into the lenses of the patient's glasses, and may be given to any patient, but are prescribed particularly for patients over 60 years of age. One doctor of my acquaintance prescribes as though by a fixed rule, two diopters of base in, or one diopter in each lens, in every reading segment of two and a half or more diopters.

The viewpoint adopted in this paper is that the most important muscle deviations requiring prism correction in the glasses are those in the vertical direction. A small hyperphoria of not more than two prism diopters may give an individual many distressing symptoms, and the writer has found that even when such a hyperphoria is accompanied by considerable eso- or exophoria it is frequently the hyperphoria that is the cause of the symptoms. Even with very small hyperphorias the symptoms may be great and may be the cause of defective binocular vision. Tilting of the head toward the shoulder on the side of the hyperphoria is often observed, and this phenomenon usually indicates a vertical deviation which should be corrected.

A tendency toward vertical hyperphoria is also frequent in connection with lateral squint. This vertical deviation seems to interfere with fusion, causing the eyes to alternate as soon as the two images approach the maculas. Because these images

are not vertically aligned fusion becomes very difficult, and if a tendency toward abnormal correspondence is added to this situation, superposition of the two images becomes almost impossible. A correction of the vertical deviation may in such cases mean the difference between success or failure in teaching binocular vision and normal correspondence. The development of adduction in convergence insufficiency may also be speeded up greatly if any complicating hyperphoria is first corrected.

However, the advisability of prescribing prisms for constant wear seems to be debated by several authorities on motor anomalies. Alexander Duane¹ stated that prisms when employed for constant wear are sometimes serviceable in anomalies of the individual muscles, and particularly in vertical deviations, but they may cause mischief in convergence insufficiency or convergence excess or in divergence insufficiency, by further dissociating the very functions which are to be corrected. He warns us that prisms for constant wear are merely crutches and as such should be used only temporarily. The object is to improve the binocular visual function and to integrate the eyes in such a way as to achieve good fusion and ductions and to secure comfortable binocular vision.

William Thornwall Davis² points out that the correction of hyperphoric errors with prisms may relieve the patient's symptoms but will not cure them; and he emphasizes the importance of cure, where it is possible, because hyperphoric errors may be a serious handicap to the individual. For example, prisms in glasses would be of little help to the many youths

who wish to become aviators. The army and navy air-corps standards are high, and where the phoria is in excess of the permitted standard, entrance is not permitted. Entrance into other fields is likewise barred by muscle imbalance. The prescription of prisms in glasses for the correction of symptoms is not directly within the scope of this paper. However, since the two subjects frequently overlap, and are even confused at times, it is well to mention the problem and point out the difference between the two procedures, namely prisms for correction and prisms for the relief of symptoms.

Two very good examples for which the latter procedure is appropriate are the use of prisms in glasses for paralysis of divergence and their use for paralysis of convergence. In paralysis of convergence, prisms base in should be prescribed. In this condition the patient experiences crossed diplopia within a certain distance, usually nearer than 36 inches. The images become further separated as the object is brought closer to the eyes. The prisms are usually limited to use in near work and the amount required will be that required to superimpose the images at the reading distance. In paralysis of divergence the condition presents the opposite picture. Here binocular vision is normal from about 2 to 10 feet, outside of which diplopia exists. The double images are homonymous and become further separated the farther away the object is from the eyes. In this case prisms base out are used for distance vision and that amount of prism is provided which superimposes the images at 20 feet.

NOTES, CASES, INSTRUMENTS

DERMOID TUMOR OF THE SCLERA

LELAND F. CARTER, M.D.
Detroit

Orbital and epibulbar dermoid tumors are not so uncommon as to be extremely rare. While the orbital variety is the more frequent in occurrence, the epibulbar tumors are the more interesting since they afford more opportunity for observation and study. On the bulb their most frequent site is in the conjunctiva, where they are freely movable over the globe; next in frequency are those firmly fixed at the corneoscleral junction. In the literature and in the textbooks (Duke-Elder,¹ Parsons,² American Encyclopedia of Ophthalmology) little or no mention is made of dermoids of the sclera.

Duke-Elder¹ and Collins and Mayou³ state that, "on the surface of the eyeball in the upper outer quadrant congenital growths are sometimes found containing bone, hyaline cartilage, or acini-tubular gland tissue resembling lacrimal gland. These growths are entirely in the conjunctiva being freely movable over the sclerotic. . . ." A tumor similar in appearance except that it had its origin in the lower temporal quadrant of the sclera is here described.

CASE REPORT

A male infant, 24 hours old, was seen in consultation. A small, round, angry-red tumor (5 by 4 by 3 mm.) was observed projecting between the lids of the right eye near the external canthus (fig. 1). It appeared to lie in a sulcus or "coloboma" of the lower lid from the inner surface of which a rather dense web fanned out to become firmly attached to the tumor. The lower cul-de-

sac was uninvolved, a probe could be passed freely between the tumor and the lid. The tumor was hour-glass shaped with its base firmly attached to the sclera.

The parents were advised to postpone removal for several months, when the child could safely be given a general anesthetic. Ten days later, because of the

Fig. 1 (Carter). Dermoid tumor of the sclera in a 10-day-old infant.

anxiety of the parents, operation for removal of the growth was performed under local anesthesia (pontocaine, 0.5 percent; novocaine, 2 percent). Attempts to inject the scleral attachment of the tumor were unsuccessful because of the bony hardness. The surrounding bulbar conjunctiva and lid attachment were infiltrated with novocaine, and one large conjunctival vessel going to the tumor was tied off.

The weblike connection between the lid and the tumor was severed at the lid margin, giving free access to the growth. After several attempts, the tumor was finally cut through with a pair of Stevens scissors flush with the sur-

rounding sclera. A dark bony base remained, no doubt a portion of the tumor, but no effort to remove more tissue was made for fear of entering the globe. The wound was closed by two overlapping conjunctival flaps. The rounded edges of

of ulceration with some associated small round and polymorphonuclear cell infiltration about the ulcer. There are sebaceous glands, an occasional one being dilated, and a few sweat glands. There are numerous groups of tubulo-alveolar

Fig. 2 (Carter). Photomicrograph of dermoid tumor of the sclera, showing epidermis, sebaceous glands, and bone.

the V-shaped "coloboma" of the lid were scarified and the defect closed by four interrupted black-silk sutures, two through the tarsal plate, one mattress suture through the lid margin, and one through the skin.

Recovery was uneventful and the sutures were removed on the tenth post-operative day.

Microscopic examination: "The specimen (fig. 2) is skin and subcutis. The epidermis is thickened and has one area

glands, apparently well differentiated lacrimal glands. In the center of the piece there is a mass of bone and osteoid tissue in association with a proliferation of anaplastic cells which have hyperchromic nuclei, little cytoplasm, and which are quite variable in shape. This tumor is malignant.

"Diagnosis: Mixed lacrimal-gland tumor with malignant changes."

Drs. Parker Heath and Plyn Morris were of the opinion that considering the

age of the patient the character of the cells was not unusual. In their opinion the tumor was a nonmalignant dermoid.

COMMENT

Dermoids of this character have generally been classified as teratomas, but Collins and Mayou choose to regard them as an atavism of tissue, since the corium of the skin in some animals is capable of producing cartilage and bone in the form of the exoskeleton. To them the Verneuil theory of dermal inclusion

inclusion theory. The fact remains, however, that there was in appearance no apparent loss of lid substance and that upon repair, as in any simple laceration, there was no shortening of the lid.

Thus on the basis of these findings one might assume that an amniotic band or bands gave rise not only to the tumor but were instrumental in a mechanical way in bringing about the lid defect.

Twelve months following removal of the growth (fig. 3) there is a moderate thickening of the conjunctiva in the

Fig. 3 (Carter). Appearance of eye 12 months after removal of tumor.

seems the most logical. Parsons² also expressed it as his opinion that this theory was strongly supported by the site of the election of these tumors, situated as they are at or near the fetal clefts or sutures. That a certain number of them represent the residue of amniotic bands, Duke-Elder¹ is "tolerably certain."

In the case here under consideration Herrenschwand's hypothesis of an organic adhesion of the lid margin to the surface of the globe as a possible cause is in part at least borne out by the rather heavy bridge of tissue spanning the cul-de-sac from lid margin to tumor. On the other hand, the fact that the lid defect was in such intimate contact with the tumor lends ample support to the dermal-

lower temporal quadrant but no evidence of recurrence. The fundus is entirely normal except for some grayish discoloration, but there is no elevation of the choroid at the extreme periphery in the lower temporal region. There are no colobomata of the iris or choroid nor other congenital anomalies. The left eye is normal.

A somewhat similar dermoid cyst, the base of which was "substituted for the conjunctiva, sclera, and choroid coats of the eye," was described by Miller.⁴ An interesting case report was also published by Calhoun⁵ of a dermoid tumor of the cornea and conjunctiva associated with a scleral ectasia in the lower nasal quadrant.

SUMMARY

An unusual case of congenital epibulbar tumor is described which involves the conjunctival, scleral, and probably choroidal coats of the eye. The microscopic section showed the presence of cutaneous and subcutaneous tissue, sebaceous and sweat glands, numerous groups

of tubulo-alveolar (lacrimal) glands, and a central mass of bone tissue. There is associated with this a "coloboma" of the lower lid.

Three possible causes of such a tumor are described, but no definite conclusion has been drawn in this instance.

THE TECHNIQUE OF TONOM- ETRY AND CARE OF TONOMETERS

MARK J. SCHOENBERG, M.D.
New York

Possession of an accurate tonometer, proper care of the instrument, correct technique in using it, and complete recording of the tonometric findings are the four requisites of reliable tonometry.

Since neither textbooks nor ophthalmologic magazines contain explicit instructions concerning the subject mentioned in the title of this paper, the author has deemed advisable to submit the rules followed at the Glaucoma Clinic of the Manhattan Eye and Ear Hospital of New York.*

The tonometer. The instrument must be reliable, certified as to accuracy of performance by a recognized "checking station."

The care of the instrument. The tonometer must be kept *clean* and *aseptic*—

the same rule applies to the box in which it is deposited.

Cleansing is effected by wiping the interior of the cylinder, the foot plate, the foot of the plunger, and the testing block—first with a piece of cotton wound tightly around a toothpick and immersed in 50-percent grain alcohol, then rinsed off with sterile water and dried with cotton.

This procedure must be followed after each tonometric examination and, again, once before the day's consultation hours. (Now that epidemic keratoconjunctivitis is prevalent in many sections of the country, it is timely to warn against infractions of the rules of asepsis.)

If available a separate tonometer should be used for septic cases; if not available, the tonometer must be cleansed with great care after such measurements; if only the one eye is infected, the tonometer should be applied first on the clean eye.

Technique of tonometry. (a) The examiner washes his hands with soap and water before and after each tonometry. (b) The instrument is to be manipulated gently by holding the handle between the thumb and adjoining two fingers—the

* The Glaucoma Clinic at the Manhattan Eye and Ear Hospital of New York is sponsored by the National Society for the Prevention of Blindness.

pointer and hammer are not to be handled. (c) Check the tonometer on the testing block to see whether the pointer stops at the zero division. (d) In applying the instrument, the examiner faces it squarely so as to avoid a parallax error in reading the scale. (e) He holds the instrument *vertically*, so that the axis of the patient's eyeball and that of the tonometer are in one straight line. (f) The foot plate must cover as exactly as possible the center of the cornea. (g) The eyelids are gently separated without the exertion of any pressure on the eyeball. (h) If the eyeball is deeply set in the orbit, it is often necessary to obtain the help of an assistant, who pulls down gently the lower lid while the examiner retracts the upper lid, just enough to allow the foot plate to cover the central portion of the cornea. (i) The entire procedure is to be made in a calm and gentle manner, so that the patient should be given a chance to coöperate without becoming anxious or tense. (j) If the instrument and the technique are correct and if the patient is relaxed and coöperative, two or three consecutive applications (of the tonometer) will give the same reading or a difference not greater than one-half a division. (k) Avoid covering the patient's second eye in the process of keeping the lids apart, or with the hand holding the tonometer.

The patient is placed on a table or reclining chair with the face directed straight up; the collar is loosened to prevent pressure on the jugular vein, thereby increasing the intraocular pressure.

One drop of a weak anesthetic (ponto-caine 0.25 to 0.50 percent or butyn 0.50 percent) is instilled twice at an interval of 10 seconds (preferably above the limbus corneae while the patient is looking down). Ready, within one minute, the patient is told to direct his eyes straight up to a target on the ceiling or preferably to his own hand, held in a suitable posi-

tion indicated by the examiner. Any deviation from the straight-up position leads to errors in measurement. In some apprehensive patients, coöperation and steadiness of gaze are secured by asking the patient to watch the target, whether it changes color during the examination ("whether it is becoming blue or green"). This induces the patient to concentrate on something else than on his own fear.

Unruly or overanxious patients have to be carefully trained before the tonometric reading can be relied upon; this applies especially to one-eyed patients.

At the conclusion of the procedure, one drop of 10-percent argyrol is instilled in each conjunctival sac and the eyes are irrigated with salt or boracic-acid solution—just enough to clear the eye of some of the argyrol. (In very rare cases, patients are allergic to argyrol.)

Recording the tonometric findings. The following data must be recorded: (a) date and hour of day; (b) the reading on the scale; (c) the number of hours or days since last instillation of the miotic; (d) the name and dosage of the drug used; (e) the strength of the miotic and frequency of instillations.

A NEW SUTURE FOR USE IN MUSCLE-RECESSION OPERATIONS

CLARANCE B. FOSTER, CAPT.
(M.C.), A.U.S.

New York

For some time, Wendell Hughes of New York and others have used, in children, a modification of the Jamison technique. A double-armed suture is placed vertically, passing through the superficial layers of sclera, crosswise to the direction of the fibers, at the point of selection. The suture is passed through correspond-

ing points in the muscle and tied in a surgeon's knot.

The writer has used this method in adults with uniformly good results.

A further simplification and extension of the modification is now suggested.

Before the tendon is cut, and after the muscle hook has isolated the tendon, and is still in place, a single-armed suture on a cutting-edge needle is passed through the tendon, about one fourth of the distance from one edge, from scleral side toward conjunctival side, and back through the tendon toward the sclera, at a corresponding point one fourth of the distance in from the opposite edge. This may sound complicated, however it is extremely simple. Lifting the muscle hook like a lever exposes the required edge of tendon and provides plenty of space for the passing of the needle. The tendon can then be severed from its scleral attach-

ment, the suture being retained as a stay suture. At the point of selection, the scleral bite crosswise to the scleral fibers can be made, going, of course, in the direction opposite to that of the initial passage through the tendon. Upon emergence from the scleral fibers, the suture is passed from scleral side to conjunctival side through the tendon, just inside the first entry. The suture can then be tied without too much tension. The tendon is well flattened down and in good approximation to the sclera.

This method has the advantage of using only one suture, and that of a saving of tendon. (Many small recessions are neutralized by the shortening involved in placing sutures behind a muscle clamp.) It can also be used in cases where a muscle clamp is not available. The value of such a procedure in war surgery is obvious.

SYMPOSIUM ON HEAD AND FACE PAINS
(Abstract of Proceedings)

INTERNAL MEDICINE

DR. G. W. SCUPHAM. The lay public has been so well educated to the fact that eye strain and eye diseases are frequent causes of headache that they will go to the ophthalmologist, and the otologist has his turn because of the belief that sinus headaches are common. It is a difficult problem because of the multiplicity of causes of which headache is the outstanding symptom. From the standpoint of the internist, not only is the diagnosis difficult, but the therapeutic problem is often more so. If we limit ourselves to any one of the fields of medicine in which headache is important we are likely to fail to arrive at a conclusion in a particular case.

A number of mechanisms may result in various types of headache, but so far as head and face pains are concerned, these are not so important. Pain may be the result of local diseases or local reflex phenomena. Some blood-vessel disorders are characterized by pain. Arteritis of the temporal vessels does result in a throbbing, burning type of pain localized

in the region of these vessels, often associated with evidence of an inflammatory process. Herpes zoster is a fairly common cause of head pain. Tumors of the scalp and skull, multiple myeloma, and osteitis of the skull might also be mentioned.

Headaches are more important to the internist than head and face pains. The character of the pain seems to be different. Headache arises within the head, whereas head and face pains are more or less superficial. Headache is extremely variable in different individuals. It is uncommon in children, and in aged individuals it is less common than in middle adult life.

The majority of headaches are those which are merely part of the general symptomatology of the disease picture. In almost all acute infections headache is an important symptom. Typhoid fever is often characterized by long-continued headache; influenza and acute respiratory infections by headache at the onset. An example of toxic headache is that resulting from sulfathiazole; alcohol is also a cause of this type; carbon-monoxide poisoning is also toxic, but often results in structural changes. In acute nephritis, headache, associated with nausea, is an important symptom of the onset of the disease. It is in part toxic but there may be a rise in intracranial tension; in the uremic phase of chronic nephritis the headache is probably toxic. Headache is a common and extremely important symptom in chronic malaria, is persistent and severe, and disappears with control of the disease.

Hypertension is the major vascular disease in which headache is important. The

inhalation of amyl nitrite results in headache and fall of blood pressure. This is an interesting contrast in the mechanism of headache, as in persons having hypertension a fall in blood pressure often overcomes the headache. Many with severe hypertension never have headache, and many with moderate hypertension complain of severe throbbing headache, often continuing for days without marked exacerbation of the blood pressure. In general, patients whose hypertension is in the malignant stage are subject to severe headache, probably because there is marked vasoconstriction of the arterioles of the central nervous system.

The headache that resembles the type caused by injection of histamine, may be confused with migraine because it is often unilateral. There is no history of familial headache. The headache often begins at night. There is often flushing of the head and face on that side, tenderness of the temple and over the carotid artery. Pressure on the carotid may result in relief. A small amount of histamine injected subcutaneously can initiate an attack. The recognition of this type is important because relief may be obtained by the therapeutic administration of histamine.

There are a great variety of rheumatic headaches, from that of acute rheumatic fever, which may be mistaken for brain tumor, to a mild occipital headache of chronic nature. Perhaps the common type is associated with fibrositis and myositis as well as with cervical osteoarthritis. Such headaches occur with increased tension of the muscles of the spine and neck.

Reflex headache is more difficult to differentiate. It is often associated with disease of the pelvic structures. Constipation is said to cause headache reflexly and evacuation of the lower bowel brings relief.

The typical features of migraine headache are well known. The family history

is so common that if we do not find it we doubt the diagnosis. There is a slow development of headache with nausea and vomiting, relief and sleep, often preceded by aura. It is extremely variable in some individuals, and it sometimes disappears at or near the menopause. Another striking feature is the association with the menstrual cycle. Migraine may be precipitated by a wide variety of factors; food allergy, emotional states, certain endocrine abnormalities, particularly the gonadotropic factor, fatigue, infection, and many others. It is commonly thought to be incurable, but much can be done if the problem is studied. Treatment should be directed toward elimination of the exciting factors when possible.

NEUROLOGY

DR. LEWIS J. POLLOCK. When a stimulus is applied to the skin or mucous membrane on the exterior of the body, sensation is transmitted by the sensory fibers of the craniospinal nerves and reaches consciousness directly through their appropriate sensory tracts. Thus, inflammatory and other pathologic processes of the skin and mucous membrane produce stimuli carried by ordinary sensory cutaneous nerves and are localized by one to the area stimulated.

When the subcutaneous areas are stimulated, sensation is transmitted in two ways: first, by the ordinary sensory components of craniospinal nerves carrying deep sensibility—in the case of the head and face, by way of the sensory components of the 3d, 4th, 5th, 6th, 7th, 9th, 10th, 11th, and 12th cranial nerves; second by a more complicated mechanism producing referred pain—as an example the shoulder-tip pain occurring when the central portion of the diaphragm is stimulated by diaphragmatic pleurisy. The impulse travels by way of the phrenic nerve through the posterior roots of the 4th

and 5th cervical nerves to the spinal cord, there making a synapse with the descending short fiber tracts to the points of origin of the cervical sympathetics, then through the preganglionic and postganglionic fibers to the skin, where a chemical change is produced stimulating the sensory end organs, and sensation is then carried by the sensory spinal nerves into the spinal cord and by its appropriate sensory tract into consciousness. The location of pain is then referred to the skin over the shoulder tip.

The same mechanism applies to the head and face. In the case of vascular headaches, and perhaps migraine, stimuli occur as the result of dilatation of the blood vessels; impulses travel by way of the *nervi vasculorum* originating in the cranial nerves, perhaps also upper cervical, and find their way into the brain stem and medulla; there a synapse with the short descending pathway of the cervical sympathetics occurs; impulses are sent over the postganglionic fibers to the skin, where again chemical changes produce a stimulus in that area, and impulses carried by the particular sensory nerve involved, chiefly the fifth but also others, enter the brain stem. This holds true also of distention of other subcutaneous tissue as well as traction on the meninges and dural sinuses. This can be proved by experiments in which the pain ensuing from faradic stimulation of the superior cervical ganglion can be stopped by section of the sensory root of the fifth nerve. The pain cannot be stopped by severing the preganglionic fibers when the appropriate anterior roots are severed or by cutting the cervical sympathetic chain below the superior cervical ganglion.

Usually head pain does not occur as the principal symptom of intracranial disease; although headache may be the presenting symptom, it is not the sole symptom in intracranial tumors. Diplopia,

hemiparesis, facial paresis, ataxia, loss of visual acuity, vomiting, and mental disturbances are always at times associated with the headache. Headache when present is associated with vomiting which may be projectile in character and usually does not lead to alleviation of pain. Here the headache is sharp and severe and continuous; it may be a throbbing, stabbing, boring pain. It is often brought on by sudden change of posture and may disappear by changing the position of the head; in intraventricular and infratentorial tumors, the patient may hold his head in a position which tends to lessen the possibility of occurrence of pain. It may be associated with suboccipital tenderness and rigidity of the neck. It is increased on jolting and straining and, with sudden exacerbation of pain, vomiting may occur.

The location of pain is not characteristic, nor is it an index of localization of the tumor. The character of the tumor may influence the type of headache and its severity. Rapidly growing tumors are associated with more headaches; hard tumors cause more pain; circumscribed tumors produce pain of greater intensity than do infiltrating tumors. Tenderness to percussion of the skull at times serves to bring out an area of circumscribed tenderness which may indicate intracranial disease.

Associated signs and symptoms lead to the diagnosis. Hemiplegia of sudden onset points to hemorrhage, thrombus, and embolism; the sudden onset of excruciating suboccipital pain with loss of consciousness, rarely hemiplegia, and rigidity of the neck, characterize subarachnoid hemorrhage, usually due to ruptured cerebral aneurysm. Inflammation of the leptomeninges, alone or with encephalitis, is associated with rigidity of the neck, Kernig's sign, and Brudzinski's sign; and evidence of inflammatory disease is found on examination of the cerebrospinal fluid.

Serous meningitis with paroxysmal hydrocephalus is characterized by the occurrence of definite attacks of headache, vomiting, sometimes choked discs, and signs of interference with cerebral function. Such attacks, after a relatively short course, may disappear and a considerable time elapse before another occurs. In such cases one may often obtain a history of another phenomenon of anaphylaxis, as angioneurotic edema or Menière's syndrome.

Most cerebral diseases produce interference with function of motion, sensation, tone, synergy, speech, reflexes, and cranial nerves. No more than a consistent difference in the activity of deep reflexes upon the two sides may be noted, but when this is combined with diminished superficial reflexes on the same side it is a strong indication of organic disease. Changes in the visual field may be found long preceding change in the optic nerve, especially in temporal-lobe lesions, wherein a quadrantic anopsia and a headache may be the sole symptoms of tumor. Whether encephalitis uncomplicated by meningitis can produce headache cannot be stated. Many of the encephalitides are associated with meningitis, and in lead encephalopathy a marked change in renal function may be present, which in itself may produce marked headache.

In a very large number of patients suffering from headache careful search reveals no organic disease. Such headaches may be termed "psychogenic," or, perhaps better, headaches associated with neurosis. Usually the patient does not mean that he has pain in the head when he complains of headache. It is a feeling sometimes describable, at times not; always it is "intense," "terrible," "horrible," "splitting," "unbearable." It is the hyperbole and exaggeration which point to the condition. The sensations complained of

are also myriad. The so-called pain may involve any part of the head, and shifts from day to day or from hour to hour. It is continuous, is usually unaffected by weather or by ordinary changes in position. It is not accompanied by nausea or vomiting. It is always increased by making decisions and always by work. It is relieved by reassurance, whether by a physician's statement or by favorable observations by the patient. If the patient becomes interested in any pursuit, so long as the interest lasts the headache will abate; it is abated by any new treatment or doctrine. It is worse in crowds, and is increased by excitement, disputes, quarrels, and domestic, social, and business conflicts.

As is the case with sensations relative to phobias relating to the heart or stomach, so with this headache. A real pain or discomfort of organic origin may often have preceded it; it may follow a migraine, an indurative, ocular, or sinus headache, or may coexist with them. Prominent among the symptoms are depression, abulia, inattention, difficulty in concentration, forgetfulness, introspection, anxiety, fears, indecision, fatigue, and insomnia. It is important not only to distinguish these headaches from organic headaches, but it must be remembered that they may be the beginning of a more serious condition, a beginning melancholia, dementia praecox, or dementia paralytica.

Often pain in the head or certain types of headache are classified as neuralgia; namely, auriculotemporal, occipital, and so on, neuralgia. This I believe is a mistake. If we accept trifacial neuralgia as characteristic of the neuralgias, then sudden paroxysms of severe pain in the distribution of the sensory supply of the nerve, lasting only a fraction of a second, and brought about by touching a

trigger or algigenetic zone, are seen only in relation to the trigeminal or glosso-pharyngeal nerve.

The characteristic neuralgia affecting the trigeminal nerve is observed usually when no underlying pathology can be demonstrated even when the gasserian ganglion is inspected. At times it occurs in relation to tumor of the gasserian ganglion, angle tumors rarely, and multiple sclerosis. It is not related to any other extraneural disease, as disease of the sinuses, teeth, or other structures of the head and face. The characteristics of the pain are unique. The pains are always referred to the same zone, supraorbital, infraorbital, or mental, or two or all of the branches. They may occur seemingly spontaneously but can always be brought on by touching the area which is the trigger zone, or by movements stimulating such a zone—talking, chewing, swallowing. The area stimulated is not always the area in which pain ensues. The pains are very severe, sharp, shooting, electriclike, last but a few seconds, or may consist of a succession of shorter ones. There is no relief other than interruption of the sensory fibers of the fifth nerve.

ALLERGY

DR. SAMUEL M. FEINBERG. From the standpoint of allergy there are two main types of headaches: the classical migraine and the simple but frequently recurring headaches. We believe there is no real etiologic distinction between the types; the migrainous are merely a more severe form. We have observed many patients whose ordinary recurrent headaches go on into migraine, and other patients whose headaches vary from the simple to the typical migraine at different times.

What is the mechanism of migraine? It has been demonstrated that angioneurotic edema produces cerebral symptoms and

that cerebral vessels have a vasomotor control. Several years ago a young woman who had violent migrainous symptoms was finally operated on for suspected brain tumor. Marked edema of the brain was noted but no tumor was found. Following the operation she had a defect in the skull. It was now observed that the onset of a migrainous attack was initiated by a preliminary pallor of the face and depression of the skull area. As the attack progressed there developed definite bulging of the decompressed area. Allergy studies showed definite clinical sensitivity to specific foods and the latter precipitated the headaches and the bulging of the defect. It would appear, therefore, that the mechanism of migraine is probably a cerebral angiospasm followed by vasodilation and increased intracranial pressure.

What evidence have we for the allergic basis for headaches? Dr. Scupham has already mentioned the great tendency to heredity in migraine. The majority of patients give a family history of migraine, but a large percentage also give a history of other allergy in the family. It is generally overlooked that in allergy not only is there a general tendency to the inheritance of allergy but a special tendency to have certain allergic manifestations predominating in the family. Antecedents with urticaria are more apt to have offspring with urticaria than other allergy; antecedents with migraine are more likely to have offspring with that disease than any other allergic manifestations. The fact that migrainous attacks are frequently precipitated by nonallergic factors such as fatigue, constipation, excitement, weather changes, and endocrine cyclic phenomena does not detract from the allergic concept of the disease. We know that such precipitating causes can be instrumental in being the "trigger" to other

allergic phenomena such as asthma, rhinitis, and urticaria. It is true that only a small proportion, perhaps a fourth, respond to skin tests, and yet we find that in some of the other allergic manifestations, such as urticaria and gastrointestinal allergy, the incidence of skin reactions is also small. By clinical means and observation we can assure ourselves that many patients have their headaches from foods in spite of negative skin reactions.

By the use of skin tests, simple observation, diary records, and restricted diets we can usually make a diagnosis. We may say conservatively that in half of these cases allergy can be demonstrated; as to the others we believe no satisfactory explanation exists at present. The majority of the allergic patients are sensitive to foods, the most common of which are wheat, milk, cocoa, peas and beans, potato, pork, egg, and onion. It should not be forgotten that inhalant allergens may also cause migraine.

ENDOCRINOLOGY

DR. HUGO R. RONY. It may be expected that endocrine glands play some role in the etiology of headache for three reasons: (1) Two glands, the hypophysis and the pineal gland, are located in the intracranial cavity; (2) hormones are known to affect secretion of the cerebrospinal fluid as well as retention of water in various tissues, including possibly the meninges and brain; (3) glands participate in a number of factors known to be concerned in the production of headache—control of blood pressure, certain metabolic processes, the autonomic nervous system, the level of sugar, calcium, sodium, and other components in the blood.

It is difficult to obtain reliable statistical data in regard to the frequency of endocrine headache, inasmuch as the diagnosis of endocrine disturbance is some-

times a matter of opinion. Further, even in the presence of definite endocrine disturbance, its role in the production of the headache in a given case may be open to question. It is probably safe to say, however, that the number of cephalalgias in which glandular disturbance is a contributory factor is quite great, whereas true or primary endocrine headache is relatively rare.

In tumors and hyperplasias of the hypophysis headache is a prominent symptom; it is more or less constant, bitemporal, or occipital. It is believed to be due to distention of or pressure upon the capsule of the gland or the dural diaphragm above the gland. Eosinophilic, basophilic, or chromophobe tumors may produce this headache regardless of the functional state—deficiency or hyperactivity—of the gland. Removal of the tumor or deep X-ray therapy may completely relieve the headache. There is some evidence that the headaches of pregnancy, artificial or natural menopause, and so-called premenstrual headaches may be of pituitary origin, probably due to mechanical effects of the hyperplasia of the gland known to occur in these conditions. Such headaches may be successfully treated by large doses of estrogenic hormone preparations which are known to exert an inhibitory effect on pituitary hyperplasia.

Tumors of the pineal gland may produce severe headache of the type seen in brain tumors, especially if they lead to compression of the Sylvian duct and cause internal hydrocephalus with consecutive increase of intracranial pressure.

Headache is not infrequent in disturbances of the thyroid gland, either hyper- or hypothyroidism. Such headaches are usually mild with no characteristic localization. That they are related to the thyroid disturbance is shown by the fact that they are relieved by specific therapy, ad-

ministration of thyroid substance in hypothyroidism, or thyroidectomy in hyperthyroidism.

Headache is a prominent symptom of Addison's disease or other forms of adrenal insufficiency, and may be relieved by administration of adrenal cortex extract. In hyperinsulinism, headache may be an element of the hypoglycemic syndrome. Characteristic of this headache is its onset when the stomach is empty, with prompt relief after food intake. Hyperglycemia, on the other hand, does not in itself produce headache; however, headache frequently accompanies diabetic acidosis, and severe headache in the uncontrolled diabetic may be a danger signal of impending coma.

Headache in various conditions of doubtful glandular etiology may present a considerable diagnostic and therapeutic problem. Thus it may be difficult to decide whether headache in patients with a hypotension-fatigue syndrome, certain ovarian disturbances, or male climacterium, and the like, is of glandular or psychogenic origin. Even therapeutic success with specific glandular preparations may not answer the question of the nature of the headache, in view of the possible suggestive effect of treatment. In certain forms of obesity, especially when accompanied by hyperostosis frontalis interna (Morel's syndrome) or by painful lipomatosis (Dercum's disease) headache may be a prominent complaint. Reduction of weight in such cases is usually followed by more or less complete relief of the headache, probably because of the lowering of blood pressure and lessening of water retention as a result of loss of weight.

OPHTHALMOLOGY

DR. BEULAH CUSHMAN. Patients with headache come to the ophthalmologist

sooner or later, as it has become almost a maxim that errors of refraction and muscle balance cause headache and asthenopia, and this belief is fostered by advertisements. The eye is particularly sensitive to neurosis since it is a highly specialized organ.

Of the 12 cranial nerves 4 go directly to the eye and 3 have distributions to the eye. The extensive distribution of the fifth nerve from the midbrain down to the second cervical level and the numerous interrelationships which it forms with the nuclei of origin of all the other cranial nerves, constitutes one reason why headaches so frequently result from many different causes and are so vague in distribution. The association of the trigeminus with the vagus accounts for the vomiting which accompanies acute glaucoma. This also explains the relief of dyspepsia obtained by proper correction of errors of refraction and muscle balance.

Ocular headaches have been divided into three groups: those due to retinal irritation, those due to organic disease, and those due to eyestrain.

Retinal irritation may follow glare with any sudden change of environment from a dull to a bright light, or with the use of a torch in industry. The range of sensitivity varies with the individual, partly according to the amount of pigment in the retinal pigment layer and choroid. Ophthalmic migraine, a rare condition, may be precipitated by glare, and is the type which has been described as associated with palsy of an ocular nerve, generally the third; at first the palsy is temporary, later becoming permanent. The pain is diffuse, beginning in the temporal region and spreading to the occiput. Pain and nausea always precede the paralysis. The pain in ophthalmic migraine is usually on the same side as the hemianopia, whereas in typical mi-

graine the pain is on the opposite side. The paralysis, which may involve the iris and muscle of accommodation, usually passes off in the first attack. The attacks occur only a few times during the patient's life, but each attack may continue for days, weeks, or months. The involvement of the oculomotor nerve has been constant in all published cases, but the pathologic pictures show no uniformity.

Organic diseases produce ocular pain according to the degree of abnormality of the ocular nerves and muscles. Foreign-body sensation and discharge are present with inflammation of the conjunctiva, cornea, and sclera.

Ciliary neuralgia is the type of pain present with iritis and cyclitis, is usually worse at night, and varies in intensity. Neuralgia of the eye has also been described as pain on movement of the eye and tenderness of the ocular muscles after exposure to cold air. Closely allied to this condition is neuralgia of the forehead. The symptoms may be associated with transient paresis, which responds to heat and salicylates.

The pain in acute glaucoma extends along the distribution of the fifth nerve. In cases of chronic glaucoma and secondary glaucoma there may be neuralgic type of pain referred to the face, cheek, and temporal areas, often mistaken for sinus infection until the vision becomes affected.

Retrobulbar neuritis produces a pain deep in the orbit, increased upon rotation of the eye; this pain may be present several days before blurred vision develops.

Pain in proptosis, as found in thyrotoxicosis, orbital tumor, and cellulitis, varies according to the degree of distortion of the ocular muscles and nerves and exposure of the cornea.

A refractive defect present for many years is unlikely suddenly to exert a malign influence according to Butler, unless

some other factor is added—overstudy, work under unfavorable conditions, debilitating illness, and psychic disturbances. Headaches of recent origin should be due to a recent cause.

Ophthalmic headaches are presumed to be due to overwork of the muscles of accommodation and fixation; the height of pain is reached late in the day and disappears after rest. The infrequency of headaches in persons with monocular vision is said to be due to absence of effort made for fusion through complex actions. Overaction of the ciliary muscles controlling accommodation producing fatigue and spasm may be followed by headache. Refractive errors predispose to headache, as does muscle imbalance. The insertion of the frontalis muscle into the upper lid of each eye participates in the contraction of the orbicularis palpebralis; the frontalis on contraction pulls on the epicranial fascia, and this in turn pulls on the occipital muscles causing fatigue and spasm.

Headaches of ocular origin are probably most often found in the presbyopic who have a receding near point. Many persons complain of ocular discomfort, who have high degrees of hypermetropia and astigmatism or heterophoria, which had caused no previous handicap. Aniseikonia is a cause of discomfort in patients with unrelieved symptoms of asthenopia or photophobia. This may be suspected in anisometropia in unequal accommodation with lenses of unequal curve or thickness, space-perception anomalies; and in the patient with good vision in each eye who prefers to use one eye only and occasionally in a patient with reading disabilities or migraine.

OTOLARYNGOLOGY

DR. ARTHUR W. PROETZ. Reliable statistics indicate that probably less than 5 percent of headaches are due to sinus

trouble. Undue emphasis has been given to sinus headache by the public, which has been recently plied with semitechnical literature on sinusitis while being kept in ignorance of the other 30 causes of headache. The physician must guard against accepting the patient's diagnosis merely because some sinus infection is present. Many people have headache; many people have sinus infection; the two are often not related.

While the mechanism of headache is not known, much light has been thrown upon it in recent years. It is usually associated with stretching or distortion of certain definite portions of the meninges or with the dilatation of certain arteries, notably the middle meningeal. The sinuses are closely related to these structures. Congestion and inflammation in the sinuses may produce typical headache.

However, these disturbances may not be peculiar to the sinuses themselves but may be of a vascular nature and result from conditions elsewhere in the body. It is my impression that there are people who are headache subjects; that is, that many stimuli of various types produce vasomotor disturbances which set up the headache mechanism and produce the symptom typical of the individual.

Mere stretching of the nasal mucosa does not produce pain. A number of cases have now been observed of sudden edema stretching the sinus lining to 10 times its normal thickness without inducing any subjective symptoms. It does not follow that stretching of the periosteum would be painless. This may be analogous to a diffuse otitis externa, which is exceedingly painful.

The existence of a "vacuum" pain of any duration is open to doubt. I can find no evidence in the literature of any experimental proof that it exists. No physiologist whom I have consulted is willing to say that the sinus mucosa absorbs oxy-

gen. It is pointed out that a system of tissues may react specifically in absorption or secretion of a gas. If no selective action exists and only the usual exchange of gases occurs in a sinus, then as much carbon dioxide must be given off by the membrane as the oxygen which it absorbs, and since carbon dioxide has a slightly greater volume than oxygen, a *positive* pressure must result if the ostium is closed.

Another mechanism may be at work which I have not seen described: sudden engorgement or sudden collapse of a sinus membrane in the presence of a closed ostium may conceivably produce positive or negative pressures. Whether these produce headache I do not know. In certain individuals slight exhaustion of air from the nasal fossae does produce headache.

Observation of pain in cases of known acute sinus activity, namely, acute empyema of the frontal and maxillary sinuses, leads to the conclusion that pressure *on an acutely inflamed area* causes severe pain. When the pressure is relieved the character of the pain changes. Although the mucosa is still acutely sore, the pain in no way resembles a so-called sinus headache as we understand it. It is not gone in half an hour. We are led to the conclusion that sinus headaches which come and go are the result of vascular disturbances (in or out of the sinus) and not of a fixed pathologic change.

Some nasal headaches can be demonstrated to result from the impaction of jets of air during inspiration against the nasal ganglion or its tributaries. These jets are the result of constricted airways. The direction is determined by the topography of the nose and its irregularities.

It is difficult to obtain a balanced viewpoint from the literature on headache. Many authors are themselves victims of the malady and their accounts and inter-

pretations are often highly tinged with their own experiences. This is entirely understandable, since a symptom so completely subjective can in any case be best studied by its victims.

There remains the problem of practical approach. Anyone seeing many headache patients (and who does not) must be struck by the fact that these people are prone to make their own diagnoses, which lead them to the rhinologist or the ophthalmologist or the dentist or the allergist or, what is more likely, to all of them in succession. They are commonly told, "It isn't your eyes, it must be your sinuses," or "It isn't your sinuses, it must be your teeth." They are seldom told, "Your headache is due to one or two or more of some 30 possible causes and we will try to find out which one it is."

In my own hands, the most direct method of arriving at some indication of the nature of a headache is a complete history both of the headache from the standpoint of the attack and of the background, and of the patient in general. A complete printed questionnaire helps greatly to visualize the case as a whole and to evaluate it. Important also is a complete daily record of the patient's contacts, diet, and activities. Again, a prepared chart with which I am thoroughly familiar has many advantages over a haphazard diary or even a carefully recorded diary according to some system devised by the patient. Since the important points in such a diary are often the minute details, standardized records are of great help.

(Copies of the forms used were projected on the screen.)

In the treatment of vascular headache and, in fact, of some others, to afford relief while investigation is going on, I find ^ephedrine with one of the barbiturates, by mouth, very useful.

I may also add that many headaches

having the characteristics of sinus pains disappear on the administration of thyroid extract. A low basal metabolic rate is not always typical in these patients. I have commonly noted improvement on giving thyroid even when the rate was +5 or more.

Discussion. Dr. Peter Bassoe: It might have been well if someone had discussed recent research on the mechanism of headache. At the last meeting of the Chicago Neurological Society, Dr. Harold Wolff reported on the work by his group in New York. They have made innumerable experiments on people whose heads had been opened, and determined that the most sensitive areas are near blood vessels, which is analogous to what is seen in the peripheral nerves. The median and sciatic nerves with their arteries surrounded by nerve fibers are the areas most frequently affected by causalgia.

One speaker is missing on this program; no one discussed teeth. Even in this enlightened age a great many people have been deprived of teeth without good reason. One striking example was a woman with beautiful teeth, who had pain which she localized in a couple of teeth. These were found to be normal upon removal, but then the pain shifted to other teeth, which were also removed, until she had lost many teeth at the time she came under observation. On questioning it was found that she was in a disagreeable situation from which she could see no escape. It was possible to point out to her how this could be straightened out and the pain disappeared and the rest of her teeth remained.

Dr. Feinberg's remarks about edema and allergic conditions causing pain are interesting. One patient developed a syndrome of brain tumor, choked disc, vomiting, severe headache, but no localized signs. A decompression was made and he

was well and had no further symptoms. No tumor was found. He moved to another part of the country and then developed typical angioneurotic edema. Undoubtedly his symptoms of brain tumor were due to edema of the brain.

Another patient, a woman, had sudden severe brain headache, aphasia, and hemiplegia. She had been taking care of a child with scarlet fever, and brain abscess was suspected. She went into coma. The brain was explored and nothing but edema was found. She recovered, but temporary aphasia recurred at each menstrual period, so this was nothing but a severe menstrual edema.

Dr. G. W. Scupham: Dr. Feinberg's conception of migraine as being essen-

tially an allergic phenomenon is generally accepted. It is analogous to asthma in many respects. Although it is not always an allergic factor that precipitates the episode, that does not alter the pattern. Just as asthma may be precipitated by many exciting factors, entirely foreign to allergic influence, so may migraine. The endocrine aspect deserves more consideration. Just what part the endocrines play in the mechanism of production of headache it is difficult to say.

Dr. Proetz's scheme for study of the subject is splendid. When a patient has sinus infection it does not mean that this is the cause of his headache. The same is true of hypertension.

Robert Von der Heydt.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review and reports of society proceedings to *Dr. Lawrence T. Post, 640 South Kingshighway, Saint Louis 10, Missouri*. Manuscripts should be typed in double space, with wide margins.

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver, Colorado*.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

REBATES AND THE "AGENCY DISPENSING POLICY"

The Riggs Optical Company has recently announced a new program for the dispensing of glasses to the public. This program is called the Agency Dispensing Policy." While it relates chiefly to business and financial relations between the refractionist and the dispensing optician, certain features are of especial interest to all ophthalmologists in that they apparently give the refractionist the power to regulate somewhat the cost of glasses to the patient. This "Agency Dispensing Policy" as announced is as follows:

1. Dispensing service is available to members of the profession licensed to refract under the laws of the various States in which our Company does business, but

only to refractionists practicing within the territory served by our Company.

2. We act as agent for licensed refractionists who are the principals in the dispensing transactions. Occasionally we also act as agent for other dispensing accounts when properly authorized to do so, on the same basis as we act for licensed refractionists.
3. The licensed refractionist appoints us as his agent to dispense for him through the medium of an agency dispensing letter. He determines the amount to be charged and collected for his account by us, and designates the amount either through a signed pricing schedule or by specifying the amount prior to the time of each transaction.
4. Any variations from his schedule must be authorized by the refractionist and a record kept of the authorization.
5. All transactions are charged to the refractionist upon receipt of the prescription or order.
6. All transactions are for cash where credit

- is not authorized by the refractionist. Unless credit rating is assured, a sufficient deposit is obtained from the patient at the time the order is placed to cover at least the refractionist's material and service costs, and in every case all unpaid amounts are collected at the time of delivery.
7. Where the refractionist authorizes credit and requests us to do the collecting for him, it is understood that if we do so, acting as his agent, the refractionist bears all credit risks. Statements sent to the patient indicate that transactions are for the account of the refractionist.
 8. Agency dispensing accounts are settled monthly. Exceptions to this rule must be requested by the refractionist and agreed to in writing to the refractionist by our Main Office.
 9. Casual transients or "drop ins" are not served. Agency dispensing service is not rendered to patients of refractionists who have not properly authorized us to act as their dispensing agents. In no case is dispensing service rendered to any transient patients of a refractionist located outside of our territory of operations.
 10. No materials are furnished and no services are rendered unless a prescription or order has been received from the refractionist or record thereof is on file with our Company.
 11. All charges to our accounts are based on our current price lists, plus a fixed dispensing fee for the dispensing services.
 12. Agency signs describing our dispensing function and procedure are prominently displayed at each of our dispensing offices.
 13. Serially numbered receipts are tendered to patients from whom collections are made, which state that the collections are made for the account of the refractionist.
 14. The Company reserves the right to decline, through its Main Office, to act as dispensing agent for any refractionist.

August 1943

Riggs Optical Company

The dispensing of glasses to patients concerns the ophthalmologist in two respects: first, his possible participation in the profits resulting from the retail sale, the so-called "rebate system," and second, the price charged the patient for the furnished glasses, which is believed by many ophthalmologists to be excessive.

The participation of the refractionist in the sale of glasses varies between two

extremes. On the one hand, is the example of the practitioner in a small community where there is no direct outlet for the sale of glasses to the patient. There the refractionist, after completing his examination, must measure the patient for the frames, determine the type to be worn, order the finished job from the wholesale house, assume the responsibility for the cost thereof, fit the glasses, when received, on the patient, and finally be responsible for alterations and adjustments. Clearly this refractionist, forced by necessity into the position of a retailer, is entitled to the retail profit as a recompense for his services. On the other extreme is the refractionist who, after completing his refraction examination, gives the patient the prescription and directs him to an optical house to have it filled. Thereafter, his task and responsibility are limited to the usual perfunctory examination of the glasses for accuracy and fit, and to the assumption of financial responsibility in case an alteration in the original prescription is necessary, or credit is injudiciously extended to the patient. This latter contingency appears well guarded against in the "Agency Dispensing Policy." As a reward for these minor services and obligations under one guise or another, the refractionist receives back a fat share of the profit ensuing from the sale of the glasses. Disguise this transaction as you will, and distasteful as the term may be both to the refractionist and the optical house, in its last analysis this is nothing more nor less than a straight rebate. While this "Agency Dispensing Policy" is manifestly an effort to deal frankly with this problem, it is open to the criticism that it cloaks a distinctly unsavory transaction, condemned alike by the national ophthalmological societies and by the public, with the mantle of a respectable business procedure.

Certain features of the new policy are,

however, to be commended. First and foremost, it removes the veil of secrecy from the obnoxious business, and provided the patient takes the trouble to inquire into the meaning of the various placards and signs, and into the significance of the receipt given him, he may learn that the refractionist in addition to the fee paid him for professional services, is also receiving a share in the profit from the sale of the glasses. Secondly, and even more important, provided the Riggs Optical Company does not avail itself of the exit offered by "clause 14," the refractionist who does not wish to participate in the retail profits is given a weapon in "clause 3" with which he may strike at the heart of the rebate system and the excessive charge for glasses finally made to his patients.

Under this clause the refractionist is clearly given the power to determine the amount to be charged and collected from the patient for his finished glasses. While no specific limits are set, the obvious minimum would be the wholesale cost of the glasses charged to the refractionist, plus the fixed dispensing fee charged by the Riggs Optical Company (clause 11), plus a small "cushion" charge to provide against loss or subsequent change. Did the refractionist dictate such a price for the patient there could be no rebate of any kind, and the patient could receive his glasses at a considerable reduction over the present prices charged. The obvious maximum would be all the traffic would bear, subject to such ceilings as might be imposed by a government agency. In this case the refractionist would receive the maximum of rebate and the patient, accordingly, charged the maximum for his glasses. Between these two extremes are various possibilities. The refractionist, while refusing to take any rebate, might ^{we} feel the patient should properly pay a moderate mark-up on the wholesale

price, and any profit finally accruing might be turned over to a charity or some medical institution. Other refractionists, unwilling to give up entirely their profit from the sale of glasses but nevertheless anxious to reduce the final cost to the patient, might compromise the matter in setting the amount to be charged.

What the reaction of the refractionist, ophthalmologist or optometrist, will be to this new policy remains to be seen. If the refractionists avail themselves of clause 3, and set a lower scale of retail prices than those now generally prevailing, what will be the reaction of the Guild opticians who have heretofore enjoyed the former higher scale of prices? Will they be willing to accept the lower scale, and if necessary make a charge for post-sale service to compensate for their reduced income? Or will they bring pressure on the Riggs Optical Company to avail themselves of clause 14, and refuse the business of those who seek a lower-price scale for the patient? What will be the reaction of other wholesale houses to this policy? Will a movement against the present rebate system and for a lower scale of retail prices, if inaugurated in the territory serviced by the Riggs Optical Company, spread to the East and other territories not served by them?

Further developments, if any, will be most interesting to observe.

Alan C. Woods.

SPANISH OPHTHALMOLOGICAL SOCIETY

War, the great destroyer, brings to a standstill many of the finest agencies for progress, both social and scientific. Particularly those countries which must carry on the struggle upon their own soil are so involved in the sheer struggle for existence that they can find few or no op-

portunities for the refinements of civilized life.

The science and art of medicine suffer in common with other agencies for study and research. We in the United States have so far felt the scourge in smaller degree than any other great country concerned. But there is a tendency for important medical societies to suspend their meetings or to reduce the length of those meetings. Essential workers in great institutions have left for service with the armed forces. Medical journals have fewer readers, fewer scientific contributors, and therefore reduced opportunities for service. The exchange of journals and ideas between hostile countries is abolished "for the duration."

Particularly destructive of normal living is the tragic type of warfare which we call "civil war," implying warfare between citizens of the same country. When, in 1936, the forces of Franco opened their campaign against the popularly elected government of Spain, the Sociedad Oftalmologica Hispano-Americana had for thirty-two years played a distinguished part in the development of national and international ophthalmology. Founded in Madrid in 1904, it had held its first eight annual gatherings in that great city; and one of the resolutions adopted at the "Asamblea" held in 1904 in Palma, the capital of the Balearic Islands, declared the intention of holding the next Congress in Madrid, in September, 1936.

In the words of its present secretary, López Enríquez, "Two months before that date, with the labors of organization already well developed, the Glorious National Movement broke out, and it was impossible to meet again until" October 6, 1941.

The inactivity of this important scientific society (and, no doubt, of others equally important in their respective

fields) lasted not merely for the period of the civil war, but several years after peace was restored in Spain. The reason for this was apparently a fear on the part of the Falangist government that any large formal gathering, or the activities of any organization not strictly under the supervision of the government, might have mischievous consequences for national stability. The permanent administrative council of the Sociedad Oftalmologica could do nothing beyond guarding the funds of the society. Repeated applications to the government for permission to call a meeting met with refusal. "Considering the international character of the Sociedad, the society's executives were told, and in view of existing circumstances, it was proper to delay the convocation to a later date."

The nineteenth congress of the society was held in Madrid under the presidency of Dr. D. Alejandro Palomar de la Torre. The difficulties of organization encountered by the secretary, Dr. López Enríquez, included an actual lack of information concerning the majority of the members who had been listed before the civil war. The president's short address took notice of the fact that a good many distinguished foreign and national members had died since the gathering of the year 1934. No mention was made officially of some other members who, we may suppose, had gone into voluntary exile from their native land.

To the reader of the society's transactions, the urgent character of the government's refusal to permit an earlier reunion is emphasized by the following quotation from the president's address: "I appreciate that it is a duty of justice . . . to make mention of the spirit of sacrifice, disinterestedness, love of fatherland, and Christian charity, on the part of almost all Spanish ophthalmologists, from the beginning of the Glorious Move-

ment, both those whom it happened to find in the liberated zone, and those who had to carry on, and did it worthily, in the red zone."

Further reference is made to colleagues who, "at the risk of their lives and those of their families, fled from the red zone to take refuge in the liberated zone or placed themselves from the very beginning at the service of the common cause;" and also to the activities of some colleagues who, "having succeeded in escaping from the red zone, and being unable to assemble at an early date in liberated Spain, . . . held high the national banner and professional prestige in foreign countries."

It may too readily be feared that past events have not insured Spain against further fratricidal troubles. But we may rejoice that most of our Spanish colleagues are reunited for scientific activity. The twentieth congress of the Sociedad Hispano-Americana was held in Barcelona in September, 1942. Excellent programs were presented at both annual meetings, and the essays and addresses summarized, together with discussions, are well recorded in the new "Archivos de la Sociedad Oftalmologica Hispano-Americana." This journal, well printed and well edited, appears every month or two. It contains, in addition to the transactions of the annual meetings, a large number of original papers, and some abstracts from the foreign literature.

Among the original papers of the past year and a half are the following: by Leoz Ortín, Ocular phenomena of starvation (already noticed in this Journal); by J. Arjona, Subconjunctival autohemotherapy; by H. Arruga, Corneal transplants from cadaver cornea, and Finding and localizing detachments of the retina; by A. Moreu, Considerations on the ophthalmologic diagnosis of hypophyseal tumors; by A. García Miranda, Avitaminosis in ophthalmology; by M. López Enríquez, Amblyopia of starvation in the

alcohol-tobacco group; by J. Sellas Garriga, A case of retinal angiomatosis; by Palomar de la Torre and Palomar Palomar, Concerning the etiology of recurrent juvenile hemorrhages in the vitreous; and by N. Belmonte González, Residual astigmatism in the different ametropias.

W. H. Crisp.

THE LESLIE DANA MEDAL

Last October 17th, the eighteenth award of the Leslie Dana Medal was made. At a well-attended dinner at the Coronado Hotel in Saint Louis, Dr. Walter B. Lancaster became the recipient of this honor. He discussed "The pathetic cases of blindness with good visual acuity." This

Leslie Dana medal.

was an excellent address from the broad-minded viewpoint that we have learned to expect from this man. He is one of those having vision as well as good visual acuity. A man so endowed dares to be a jump ahead of the laboratory, but this is dangerous for those not having critical minds and sound judgment based on long experience.

Father Schwitalla, dean of the Saint Louis University Medical School, presided at the dinner, at which guest speakers were Drs. S. Judd Beach and Everett Goar and Mr. Lewis H. Carris, director emeritus of the National Society for the Prevention of Blindness.

A brief history of this medal may be

of interest. The endowment for the medal was given to the Missouri Association for the Blind by Mr. Leslie Dana in 1925. The trophy itself is a beautiful gold medallion designed by the noted Boston sculptor, Christian Peterson.

The award is to be made annually, based on the following considerations:

a. Long meritorious service for the conservation of vision in prevention and cure of diseases dangerous to the eyesight.

b. Research and instructions in ophthalmology and allied subjects.

c. Social service for the control of eye diseases.

d. Special discoveries in the domain of general science or medicine of exceptional importance in conservation of vision.

The procedure for selecting the winner of the medal is as follows:

The National Society for the Prevention of Blindness will canvass the ophthalmic departments of university medical schools and various other groups interested in prevention of blindness during January and February each year. From the names thus proposed the National Society staff will select a list of not less than three nor more than six persons as nominees for the Dana Medal for the ensuing year. They will also prepare a short biographic sketch for each nominee emphasizing the reason for the selection. As soon as this list of nominees is approved by the Saint Louis Society for the Blind it will be forwarded to the Association for Research in Ophthalmology, Inc., probably before April 1st. The Association for Research in Ophthalmology, Inc., can then send the list to each of its trustees asking them simply to vote one—two—three—and so on, and the person receiving the smallest total vote will receive the medal for the ensuing year. Time and place for the presentation are to be arranged by the Saint Louis Society for the Blind.

Previous recipients of the medal are: Dr. Edward Jackson, Denver, Colorado; Miss Louise Lee Schuyler, New York, New York; Dr. Lucien Howe, Buffalo, New York; Dr. Francis Park Lewis, Buffalo, New York; Dr. Ernst Fuchs, Vienna, Austria; Dr. George Edmund de Schweinitz, Philadelphia, Pennsylvania; Mr. Edward M. Van Cleve, New York, New York; Dr. William Henry Luedde, Saint Louis, Missouri; Dr. Felix de Lapersonne, Paris, France; Dr. William Hamlin Wilder, Chicago, Illinois; Dr. John M. Wheeler, New York, New York; Mrs. Winifred Hathaway, New York, New York; Dr. Ellice M. Alger, New York, New York; Dr. Edward Coleman Ellett, Memphis, Tennessee; Mr. John M. Glenn, New York, New York; Dr. Arnold H. Knapp, New York, New York; Mr. Lewis H. Carris, New York, New York.

The distinguished names on this list indicate the good judgment of those who have selected the recipients and their acceptance the honor in which the award is held.

Awards of this character are stimulating to the profession, and this is properly regarded as one of the most desirable.

Lawrence T. Post.

BOOK NOTICE

THE HUMAN EYE IN ANATOMICAL TRANSPARENCIES. By Peter Kronfield, M.D., Gladys McHugh, and Stephen Polyak, M.D. 99 pages, 34 color paintings. Rochester, N.Y., Bausch and Lomb Optical Company, 1943. Price \$6.50.

Here is a volume which comes closer successfully to achieving the goal of a worthy "atlas" of the gross anatomy of eye and orbit than any previous book on the subject. The treatise is divided into three sections. The first consists of a series of 34 colored paintings by Gladys

McHugh. These are paintings of gross anatomic dissections, done on transparent acetate at twice natural size, so that they represent a series of dissections progressing layer by layer through the eye and orbit—in front view and side view.

The accuracy of these pictures is of a high quality, and the artist has succeeded in emphasizing the different important structures in each picture. This characteristic renders the pictures excellent for the student, directly or as an aid to dissection. Each figure is accompanied by a short description of the region shown and of its chief structures.

It is somewhat difficult for the beginner to understand the topographic relations of some of the structures of the eye without the aid of sagittal sections and diagrams—for example, the relationship of orbital septum, orbicularis, levator palpebrae, and Müller's muscle—and, therefore, this volume cannot be a self-sufficient instrument for learning gross ocular anatomy. Likewise, the topographic anatomy of the lacrimal sac and nasolacrimal duct, as well as the anatomy of the zonular region, cannot be grasped readily in layer-by-layer pictures.

However, the second section of the book, an explanatory text by Dr. Peter Kronfeld, aids greatly in the elucidation of some of these more difficult phases. This text contains a systematic description, aided by black-and-white drawings, and then a topographic description, following closely the series of paintings. This portion of the book is clear, concise, and is not overburdened with the mass of mathematical data common to most anatomy texts.

The third section of the book, written by Dr. Stephen Polyak, contains a review of the history of knowledge of ocular anatomy. This makes absorbing reading, and it will undoubtedly be difficult for some readers to transport themselves

abruptly from a mass of very material, pictorial facts to the less concrete realm of historical study.

The book is heavily bound with leatherette cover. There is no advertising matter.
Benjamin Milder.

CORRESPONDENCE

ON CONVERGENCE TESTS

Nov. 13, 1943

Editor, American Journal of Ophthalmology.

I have received several inquiries referring to my article "On convergence tests," in the September, 1943, issue, asking if the angle of convergence could not be calculated, at least approximately, with reference to the Pd and without the use of trigonometric tables. The answer to this is *yes*, it can be found and with a high degree of accuracy by the radian method as follows:

Measure the Pd (interpupillary distance) and the Pcb (near point of convergence from spectacle plane—then add 25 mm.). If we call X the angle between the two visual axes at the near point of convergence, then the proportion is Pd is to Pcb as angle X is to 57.3 (57.3 degrees is the value of the radian angle). Put in

form of an equation $\frac{Pd}{Pcb} = \frac{X}{57.3}$. Say

the Pd is 62 mm., the Pcb is 95 m.,

then the equation is $\frac{62}{95} = \frac{X}{57.3}$ whence

$X = 37.4^\circ$ or $37^\circ 24'$. By the sine tables the value comes out $38^\circ 5'$. This differs by less than three fourths of one degree from the finding by the radian method. In percentage form the difference is less than 2 percent and is well within the error incident to measurements at very close range.

(Signed) Joseph I. Pascal.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

UVEAL TRACT, SYMPATHETIC DISEASE AND AQUEOUS HUMOR

Igersheimer, Joseph. Intraocular injection of sulfanilamide in a case of purulent iridocyclitis. *Amer. Jour. Ophth.*, 1943, v. 26, Oct., pp. 1045-1047. (References.)

Marback, H. A case of congenital aniridia. *Arquivos Brasileiros de Oft.*, 1942, v. 5, June, pp. 97-101.

The patient, a man aged twenty years, was the only male child of the family. He had five sisters, who were free from the defect. No record of such an anomaly could be obtained for any other member of the family in three generations. The characteristic facies included half-closed eyelids, a horizontal nystagmus, which increased in intensity with increased illumination or upon fixing either distant or near objects. The iris was entirely absent from both eyes. One half of each pupil was clear, the other half was occupied by a semiluxated lens. The right eye presented an opalescent opacity in the

lower portion of the cornea, invaded by some conjunctival vessels. The right dislocated lens was entirely opaque, its surface showing vacuoles of varying size. In the lower outer part of this lens there was a 5-mm. pigmented spot made up of deposits which were star-shaped and resembled those of remains of the pupillary membrane. A somewhat similar formation appeared at the seven-o'clock position. With +13.00 sphere each eye obtained vision of 1/6. The tension of each eye was normal. The left cornea had no opacity. The left lens resembled that of the right eye.

GLAUCOMA AND OCULAR TENSION

Ackerman, W. G., and Allen, T. D. The treatment of hereditary glaucoma. *Illinois Med. Jour.*, 1942, v. 82, Oct., pp. 295-300.

From the reported genealogical tree

it can be seen that 6 of 14 descendants from the originally affected female ancestor, in three successive generations, had glaucoma. Two of these were male. The average age of all seven affected was 11.6 years, with a span from 7 to 15 years. There was no tendency to hydrophthalmos, and no evidence of alteration of depth of the anterior chamber, or of the presence of an enlarged lens. Myopia was found in two cases. The glaucoma was of the simple chronic type. As to treatment, intraocular tension responded poorly if at all to miotics alone. As to surgical procedure iridectomy and posterior sclerotomy were found ineffective. In one patient one goniotomy has been effective for the last 29 months in one eye, whereas in the other eye five goniotomies, two cyclodialyses, and a deep root iridectomy were without result, but one iridencleisis has since controlled the condition for 19 months. Two goniotomies performed a year apart on each eye of another member of the family have apparently sufficed for nine months to date. In another, one goniotomy on the right eye, performed 18 months ago, and two on the left eye, performed 18 and 6 months ago, have controlled the condition to date. In another member a single goniotomy of the left eye has controlled tension, fields, and vision for eight months to date. The technique of goniotomy and the aftercare are described in detail. The authors add that miotics are of value in maintaining lowered tension before and after surgery. Various types of visual defect are reported. Melchior Lombardo.

Gibson, G. G. Transscleral lacrimal canaliculus transplants. *Trans. Amer. Ophth. Soc.*, 1942, v. 40, pp. 499-515.

Sixteen experimental transplants of

a portion of the lacrimal canaliculus into the sclera of dog eyes are described in detail. This procedure was developed by the author with the immediate objective of investigating the various early steps in the establishment of an epithelial tube through the sclera with the hope of finding a type of filtration operation that might be added to the operative armamentarium in the control of glaucoma.

A very cautious evaluation of the procedure is presented. After due consideration of possible objections and pitfalls, the operation was tried on a patient with advanced glaucoma who had very little vision to lose. Marked reduction in intraocular tension was produced during the first three weeks. Later the external end of the canaliculus became closed by subconjunctival scar tissue and the tension returned to its preoperative level.

The author emphasizes that the work is still in the experimental stage, but he seems satisfied of the feasibility of the procedure after certain technical improvements are made and there has been further clinical trial. (5 illustrations.) David O. Harrington.

Knighton, W. S. Reoperations for glaucoma. *Arch. of Ophth.*, 1943, v. 30, Oct., pp. 499-504.

The return of hypertension after a glaucoma operation is of fairly frequent occurrence. In such cases, the surgeon has already selected and performed the operation that he considered the most likely to succeed. The failure of the operation to control pressure leaves him with a considerable handicap. After the operation the eye is in a less favorable state because of fibrosis, mechanical difficulties, physiologic changes and other, unknown, factors. Filtration operations that have failed

may occasionally be made to work by removing plugs of uveal or scleral tissue from the fistula. Failures in filtration that result from cicatrization of the conjunctiva do not respond to attempts to reestablish filtration by again dissecting the flap. Very careful study of the eye, including gonioscopic observation, is always indicated before reoperation is attempted.

CRYSTALLINE LENS

Burch, E. P. Safeguards in cataract surgery. *Jour. Florida Med. Assoc.*, 1943, v. 29, Jan., p. 307.

Burch describes his procedures for avoiding complications in cataract surgery. These include methods of anesthesia and akinesia, and the use of corneoscleral sutures with conjunctival apron for covering the section. Retrobulbar anesthesia is advised.

T. M. Shapira.

Courtney, R. H. Endophthalmitis with secondary glaucoma accompanying absorption of the crystalline lens. *Trans. Amer. Ophth. Soc.*, 1942, v. 40, pp. 355-369.

Seven cases are reported which suggest a hitherto unrecognized clinical entity: namely, a late endophthalmitis in one eye due to sensitivity to lens protein, the latter having resulted from an operation on the fellow eye some years previously. The author believes that spontaneous rupture of the lens capsule, found clinically in one case and histologically in another, is the causative factor. The patients showed hypersensitivity to lens protein and in two instances there was evidence of spontaneous rupture of the lens capsule. The cases reported exhibited the

following clinical picture: (1) marked ciliary injection; (2) heavy keratic precipitates of the epithelioid type, the precipitates occasionally being so numerous and so large as to coalesce and obscure any view of the interior of the eye; (3) markedly increased intraocular tension; (4) greatly increased sensitivity to lens protein; (5) unmistakable evidence of spontaneous rupture of the lens capsule. When it is clear that the endophthalmitis results from absorption of the lens cortex, the correct treatment is removal of the lens matter by operation, an intracapsular extraction being highly desirable. Failing this, the use of thorough irrigation of the anterior chamber is urged. In the author's cases, after removal of the lens from the eye all the foregoing signs of endophthalmitis and secondary glaucoma disappeared by the time of the first dressing, and convalescence was uneventful. (5 illustrations, references.)

David O. Harrington.

Moehle, Walter. The use of conjunctival flaps in cataract extraction. *Trans. Amer. Ophth. Soc.*, 1942, v. 40, pp. 527-546.

After a fairly comprehensive review of the history and literature of conjunctival flaps in cataract surgery, the author presents his own technique of extraction of the lens through a vertical conjunctival slit. He feels that this method embodies certain distinct advantages as follows: (1) The conjunctiva alone is undermined. (2) Unnecessary conjunctival bleeding is avoided by the direction of incision. (3) Keratome incision into the anterior chamber and enlargement of the incision with scissors is easily accomplished. (4) Suture control of the wound lips is easy. (5) Iris and lens capsule are easily accessible. (6) Eversion of the

cornea is impossible. (7) Prolapse of the iris is diminished in frequency. (8) There is less danger of vitreous loss. (9) Healing is accelerated and post-operative astigmatism is reduced.

All extractions were through keratome incision enlarged by scissors, with full iridectomy and extracapsular extraction. (One illustration, extensive statistical tables, bibliography.)

RETINA AND VITREOUS

Campos, Evaldo. **Neuroretinitis with macular star.** *Arquivos Brasileiros de Oft.*, 1942, v. 5, June, pp. 131-136.

This anomaly was observed in a boy of eleven years. The vision of the right eye was reduced to light perception, without light projection. The vision of the left eye was 1.5. From the fovea, spindle-shaped white lines ran out at perfectly regular intervals, like the spokes of a wheel. The total area involved was larger than the disc, including some edema. The disc was decidedly edematous, the vessels distended, especially the veins; and there were small hemorrhagic foci in the area of edema. The urine contained only slight traces of albumen and was otherwise practically normal. The author excludes a renal origin. There were physical stigmata of syphilis, and the author is disposed to attribute the ocular condition to this disease. (11 references.)

OPTIC NERVE AND TOXIC AMBLYOPIAS

Barrenechea, S., Contardo, R., Arentsen, J., and Jasmen, A. **Treatment of optic neuritis, retrobulbar or not, with nicotinic acid.** *Oftalmologia Ibero Americana*, 1943, v. 5, no. 1, pp. 7-21 (in Spanish) and 21-29 (in English).

The author treated five cases of optic neuritis with nicotinic acid. Four of the cases were retrobulbar. The dose used was 300 mg. daily. There was rapid improvement in central vision, visual fields, perception of colors, and subjective symptoms, within the first ten days of treatment. Each case is described in detail.

12

VISUAL TRACTS AND CENTERS

Fralick, F. B. **The treatment of amblyopia.** *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1195-1197.

Hughes, E. B. C. **Injury to the opticochiasmal junction.** *Brit. Jour. Ophth.*, 1943, v. 27, Aug., pp. 367-371.

In the case here reported there was injury in the left frontal region with a fracture of the left frontal bone, traversing the left frontal sinus, running along the floor of the left anterior fossa lateral to the optic canal, and then passing down into the left middle

fossa. The course of the fracture was verified in two operative procedures. No definite fracture into the left optic canal was demonstrated and no fracture of the left anterior clinoid process was demonstrable by X ray or at the time of operation. Two days after injury, a left epidural hematoma was exposed and removed through a temporal craniotomy. Postoperatively, there was severe loss of vision in the left eye and a partial third-nerve paresis. The right visual field was normal. The left visual field showed doubtful perception of light in the upper nasal field only.

A week after the operation, the patient had a clinical attack of meningitis, which lasted only a few days and responded rapidly to sulfapyridine. At this time the third-nerve paresis began to progress. It became complete thirteen days after injury. Visual acuity in the left eye had improved by this time to good counting of fingers in the upper nasal field only. The right field was passed as normal again. During the next few weeks the patient remained mentally confused, and a left frontal intracerebral aërocele was suspected and confirmed by X ray. It was not until ten weeks after the injury that the patient's condition was good enough to warrant full quantitative perimetry. A large island of vision in the upper nasal field was found on the left side, together with a little macular vision. Acuity was 1/60. In the right field, however, a large upper temporal quadrantic defect was found together with some depression in the lower temporal field. This field pattern remained stationary until the second operation, sixteen weeks after injury.

At operation, the posterior part of the anterior fossa was found to be the seat of massive adhesions extending back as far as the sphenoid ridge and

enveloping the intracranial part of the left optic nerve as far as the chiasmal junction. The chiasm itself appeared to be normal. The nerve was freed from its adhesions and the operation was terminated by drainage of the frontal cyst resulting from the aërocele.

There was a marked improvement in the patient's mental state postoperatively, and an equally startling and unexpected change took place in his visual fields. Vision in the left eye rapidly improved within fourteen days from 1/60 to 6/36. Perimetry showed this to be due to a general enlargement of the island of vision. The field in the right eye also improved until only a moderate-sized upper temporal scotoma remained.

The site of this patient's injury must have been either in the termination of the left nerve or in the anterior chiasmal angle. The lesion affected mainly the fibers of the left nerve but also caught the knee of crossed fibers from the lower nasal retina of the right eye. (Fields, references.)

Verhoeff, F. H. A new answer to the question of macular sparing. *Arch. of Ophth.*, 1943, v. 30, Oct., pp. 421-425.

The destruction of one optic tract results in splitting of the macula as detected by field tests. Apparent sparing of the macula occurs after complete destruction of one occipital lobe. This apparent sparing is explained by loss of integration between the seeing field and the blind field in the conscious visual cortical area in use. This loss results in the employment of an eccentric

retinal point for fixation and slipping of fixation occurs easily. The true macular field is actually split but field tests show it to be more or less spared.

Lesions of the optic tract do not disturb the integration between the seeing field and the blind field. In these lesions there is no eccentric fixation and splitting of the macula is therefore found in field tests. Even after complete destruction of one occipital lobe, macular splitting may be found if integration in the conscious visual area in use is not too greatly disturbed. The author states that this theory needs additional facts before it can be unreservedly accepted. John C. Long.

EYEBALL AND ORBIT

Courtney, R. H. **Endophthalmitis with secondary glaucoma accompanying absorption of the crystalline lens.** *Trans. Amer. Ophth. Soc.*, 1942, v. 40, pp. 355-369. (See Section 9, Crystalline lens.)

Dunnington, J. H. and Berke, R. N. **Exophthalmos due to chronic orbital myositis.** *Arch. of Ophth.*, 1943, v. 30, Oct., pp. 446-465.

Chronic orbital myositis has at times been described under the less desirable names of idiopathic myositis, Zeker's waxy degeneration, pseudotumor, and exophthalmic ophthalmoplegia. This condition is a nonspecific, chronic inflammatory disease of the extraocular muscles of unknown causation. Microscopic examination of the involved muscle shows lymphocytic infiltration, fibrosis, and degeneration of muscle fibers. The muscles are enlarged, pale, and cartilaginous. The disease is relatively painless unless keratitis results from exposure. There is edema of the lids, moderate to severe exophthalmos, and marked diplopia. There is distinct

limitation of motion of the eyeball, especially upward, and inelasticity of the affected muscles. The limitation of motion is best demonstrated by grasping the anesthetized eye with forceps. Strong resistance is encountered when an attempt is made to stretch the involved muscles.

There is no recognized form of treatment for chronic orbital myositis. Surgery is to be avoided if the correct diagnosis can be made, as the condition is practically always rendered worse by surgery. Radiation is not of value. The prognosis for spontaneous recovery is good if surgery is not undertaken. Treatment should be directed toward preservation of the cornea.

The authors report four cases of chronic orbital myositis. All of these patients were operated upon. A detailed pathological report on the tissues is given. All but one of the patients showed severe permanent limitation of motion. (Bibliography.)

John C. Long.

Snow, W. J. **Orbital complications in suppurative sinus disease.** *Texas State Jour. Med.*, 1943, v. 38, Jan., p. 557.

The author describes five cases with swollen lids, conjunctival edema, proptosis, displacement and fixation of the globe, and a history of recent onset. These cases were not treated uniformly, but the author is convinced that early surgery is desirable. He believes that the external ethmoidal approach affords good exposure and good drainage with a minimum of surgery. He is also of the opinion that classical operations on the sinuses should be avoided during the fulminating stage of these infections. T. M. Shapira.

EYELIDS AND LACRIMAL APPARATUS

Ellis, O. H. A combined ptosis operation. *Amer. Jour. Ophth.*, 1943, v. 26, Oct., pp. 1048-1052; also *Trans. Pacific Coast Oto-Ophth. Soc.*, 1942, 30th mtg. (5 drawings, references.)

Paula Xavier, J. de. Blepharitis and pyoctanin. *Rev. Med. do Paraná*, 1943, Jan., abstracted in *Arquivos Brasileiros de Oft.*, 1943, v. 6, April, pp. 39-42.

The generic denomination of pyoctanin includes various substances derived from anilin, endowed with cicatrizing and antiseptic qualities, without being toxic or irritating. Examples are methylene violet, auramin, methylene green, and methylene blue. The drug is used in the form of a pencil mounted in a small wooden case. Van Lint and others have advised cleaning the ciliary margin with benzine in order to remove all greasiness, then passing the pencil, moistened in 40-percent alcohol, along the roots of the lashes. The application is made every second day. The author's cases showed no example of intolerance. Any objectionable staining of the lids can be disguised by the use of tinted glasses. Failures are attributed to inadequate care as to cleansing of the lid margins. (Abstract in Portuguese by W. Belfort Mattos.)

TUMORS

Cross, A. G. Angioma of the retina. *Brit. Jour. Ophth.*, 1943, v. 27, Aug., pp. 372-373.

In the case of angiomatosis retinae now reported there was such rapid in-

crease in size within a week's time that a diagnosis of malignant growth was made and the eye was enucleated. It is probable that if the eye had not been removed retinal gliosis would have occurred, followed by complete degeneration of the eye. This case confirms the belief that angiomatous growth is the initial abnormality in cases of Hippel's disease. (One illustration, references.)

Edna M. Reynolds.

Ray, B. S., and McLean, J. M. Combined intracranial and orbital operation for retinoblastoma. *Arch. of Ophth.*, 1943, v. 30, Oct., pp. 437-445.

Extension of retinoblastoma into the optic nerve is a very common occurrence. It is believed that the standard operation of enucleation is inadequate in nearly 50 percent of cases of retinoblastoma. Exenteration of the orbit or secondary intracranial resection of the nerve is unsatisfactory. Irradiation of the stump of the optic nerve after enucleation has improved results but is not wholly satisfactory.

As the most complete method of removing the tumor, the authors propose intracranial resection of the optic nerve followed by enucleation. The intracranial operation is performed through an incision like that routinely employed by the neurosurgeons in the "hypophyseal approach". The nerve is cut at the chiasm and at the optic foramen and is removed. The optic foramen is coagulated by the electrosurgical unit and then plugged with a piece of temporal muscle. Twelve to thirteen days later the eye is enucleated. The remainder of the optic nerve is removed by traction. The intracranial operation is relatively safe and is well tolerated even by infants.

It is safer to do the intracranial operation before enucleation, because all of

the nerve and there is less danger of intracranial infection. The chief disadvantage is that in approximately 50 percent of the cases the intracranial operation is unnecessary, as enucleation shows that the nerve was not involved. The authors report the cases of two patients treated by the two-stage operation. Both patients stood the surgery very well.

16

INJURIES

Alvis, E. O. Wartime-patient phase of industrial ophthalmology. *Jour. Indiana State Med. Assoc.*, 1943, v. 36, May, p. 235.

Though statistics on the comparative increase of eye injuries since war production has been speeded up are not available, the author from his own experience feels that there has been an increase in the number of industrial eye injuries. Their number can be reduced by proper education, coöperation between employer and employee, and ample provision for making a plant physically safe. Guards, goggles, shields, and other protective devices are absolutely essential. Fluorescent lighting is considered unfavorable from a safety standpoint.

Injuries from emery, tool particles, chemicals, and actinic rays are discussed and suggestions given. Early antiseptic care of eye injuries is highly stressed. The employee is warned against the self-appointed "foreign body remover," usually a fellow employee with no regard for asepsis and whose manipulations at times end disastrously.

Francis M. Crage.

Beil, W. C. Closure of the sclera after removal of intraocular foreign body by

the posterior route. *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1210-1211,

Belfort Mattos, W. A cilium twenty years in the anterior chamber. *Arquivos Brasileiros de Oft.*, 1943, v. 6, April, pp. 38-39.

The patient, a man of 28 years, had received an injury to the right eye at the age of eight years. There was a small central leucoma of the cornea. From the center of the leucoma a filament, not unlike those seen in remains of the pupillary membrane, proceeded toward the iris. With movements of the iris, the filament became displaced on the anterior surface of that structure. There was no pericorneal injection or other anomaly. It was found impossible to seize the filament through a small opening at the edge of the cornea, but expulsion was obtained by somewhat forcible lavage. (One illustration.)

Kilgore, G. L. An experimental study of iridodialysis. *Trans. Amer. Ophth. Soc.*, 1942, v. 40, pp. 516-526.

An experimental study of the mechanism of production, the early and late clinical picture, and the prognosis of iridodialysis produced by trauma is presented.

The author concludes that iridodialysis may be produced by sudden blows on the corneal surface at or anterior to the corneoscleral limbus. The iris is

not readily torn by contusions wherein the force radiates slowly from the point of injury. Considerable damage to the intraocular tissues is associated with traumatic iridodialysis. The intraocular pathology of iridodialysis cannot be determined by the usual methods of eye examination, and a guarded prognosis should be given in such cases. (16 illustrations, references.)

David O. Harrington.

Kolen, A. A. **Soviet military ophthalmology.** *Lancet*, 1943, v. 244, June 26, p. 804.

When war broke out, base hospitals throughout the Soviet Union were equipped with X-ray apparatus and giant electromagnets. Ophthalmologists were grouped with otolaryngologists and stomatologists in order to combine the treatment of face wounds in general. The ophthalmic service was so efficient that large numbers of the ocular casualties were speedily returned to the ranks and the labor front.

For years past the clinic at Novosibirsk has paid especial attention to plastic operations. Several highly satisfactory procedures are described by Kolen, including reconstruction of the conjunctival sac without grafting of new tissue, but by stretching shrivelled surfaces, adapting a prothesis, and allowing the conjunctival tissue to proliferate so as eventually to cover the whole affected area without secondary shrinkage.

In wounds involving the orbital borders, scars can be separated, dissected out, and the gap filled with a pedicled flap taken from the adjacent subcutaneous cellular tissue. Such flaps readily became engrafted, and, without shrinking, afford excellent cosmetic results. Defects of mucous membrane of the lids, with adhesions, are repaired

by what the author calls the "transplantation flap-method" which consists of implanting upon the raw surfaces strips of mucous membrane from the lips. In reconstructing eyelids a "flap-pocket" is employed, consisting in the planting of strips of lip membrane in a pocket beneath healthy adjacent skin and, later, intercalating a slice of ear cartilage between the skin and the membrane; as a final step, all components (skin, cartilage, and mucous membrane) are transplanted by pedicle, giving in effect a ready-made lid.

Whereas surgeons have commonly deemed it wise to wait until shrinking was complete, a process frequently consuming months or years, in wartime such delays cannot be allowed. Moscow surgeons operate soon after the receipt of injuries, especially when uncomplicated by fracture or extensive suppuration; and they obtain good results even as early as two to four months after injuries are received.

Contracted scars in the temporal region adhering to the bone are likely to involve the meninges. For these and those invading the deep nasal area, where fistula or other complications might follow, special care is taken in all transplanting and the adjusting of pedicled flaps.

At the Novosibirsk clinic segments of the ciliary body have been excised, and the author cites an instance in which a ciliary sarcoma was removed without loss of sight to the affected eye. War-time successes in the same field suggest the foundation of a new operative sphere in the eye—surgery of the ciliary body.

Burton Chance.

17

SYSTEMIC DISEASES AND PARASITES

Abreu Fialho, Sylvio. *Cysticercus cellulosae* in the anterior chamber. Ar-

quivos Brasileiros de Oft., 1942, v. 5, June, p. 142. (Abstract from O Hospital, 1942, v. 21, no. 5, May.)

The original article related a case of cysticercus in the anterior chamber, with references to the national medical literature of Brazil, which records only three cases. In the case now reported, the cysticercus was in the inner part of the angle of the anterior chamber, with adhesions to the iris. Operation consisted of simple incision at the limbus above. The diagnosis was confirmed by laboratory examination. The larva was dead and the cyst calcified. The eye retained vision of 1/10.

(Abstract in Portuguese
by Alfredo Rocco.)

Constantine, E. F. **Tuberous sclerosis.** Arch. of Ophth., 1943, v. 30, Oct., pp. 494-498.

Tuberous sclerosis is a clinical entity characterized by adenoma sebaceum, convulsions, mental deficiency, and fundus lesions. The author observed this condition in a ten-year-old boy. The boy had been normal until six months of age at which time generalized twitching developed and it was noticed that he was cross-eyed. He had had several attacks diagnosed as encephalitis, and numerous generalized convulsions. He did very poorly in school and was not coöperative. On examination typical adenoma sebaceum of the face was found. There was a convergent strabismus. The vision of the right eye was 20/20-2 and of the left eye 20/400 eccentrically. The right fundus showed a large flat whitish area below the disc and a smaller similar area above the disc in which there were a few cysts. The left fundus showed three tremendous cystic swellings, one on the disc and one above and below the macula. Roentgenograms of the

skull showed several calcified areas, probably in the choroidal plexus. An electroencephalogram was suggestive of a neoplasm.

John C. Long.

Edgerton, A. E. **Herpes zoster ophthalmicus.** Trans. Amer. Ophth. Soc., 1942, v. 40, pp. 390-439.

This exhaustive treatise on the subject of herpes zoster ophthalmicus reviews the literature of the subject, including the history of the disease. The present status of the subject is outlined under the following headings: anatomy, age, sex, seasonal occurrence, exposure, prodromal symptoms, pain, vesicles, lymphatic glands, eyelids, conjunctiva, ocular complications, corneal anesthesia, cornea, intraocular tension, iris, sclera, nasal nerve, lacrimal nerve, facial nerve, sympathetic disturbances, Argyll Robertson pupil, sympathetic ophthalmia, exophthalmos, muscle paralysis, third nerve, third, fourth, and sixth nerves, bilateral cases, recurrent cases, optic-nerve involvement, other nerve involvement, types (epidemic and symptomatic), chicken pox, herpes simplex, pathology, optic nerve, retina and choroid, glaucoma, adjoining ganglia, spinal fluid and blood, prognosis, diagnosis, treatment, and conclusions.

The author reports his own cases and his experiences in diagnosis and treatment. In conclusion he presents a statistical analysis of the composite clinical and pathologic picture as gleaned from the literature. (Extensive bibliography.)

David O. Harrington.

Magalhães, Octavio de. **Scorpionism and visual apparatus.** Arquivos Brasileiros de Oft., 1942, v. 5, June, pp. 141-142. (Abstract from O Hospital, 1942, v. 21, no. 5, May.)

The article is a survey of the action of this poison upon animals and man,

from the point of view of the eye. In mild cases there are no changes in the visual apparatus, but in severe or medium cases the ocular changes are marked. They may include changes in neuromotor control, inducing nystagmus, convergent strabismus, palpebral ptosis, conjugate deviation of the eyes and the head, and disturbances of the intrinsic musculature of the eye in the form of mydriasis or miosis; sensory disturbances in the form of blindness or diminution of vision; and finally disturbances of the vascular and secretory apparatus of the eye, with lacrimation, bluish coloring of the sclera, and retinal hemorrhages.

Animal experiments are recorded. The author also reports a case of poisoning in a child of two years who had been stung by a scorpion. In this case, in spite of every attempt at treatment, including antiscorpionic serum, the child developed a generalized hypersecretion, accompanied later by blue coloring of the scleras and terminating in steady deterioration of the general condition, with acute pulmonary edema and death. The original article is said to contain a fairly abundant bibliography. (Abstract in Portuguese by Alfredo Rocco.)

Marburg, Otto. Inclusion bodies and late fate of ganglion cells in infantile amaurotic family idiocy. *Arch. of Neurology and Psychiatry*, 1943, v. 49, May, p. 708.

The author investigated the pathologic changes in infantile amaurotic family idiocy. He discovered the existence of inclusion bodies as well as severe secondary cell changes. The inclusion bodies are partly argentophilic and partly argentophobic, depending on the kind of fat which forms their basis. They are usually associated with con-

vulsive states, or myoclonia. According to their origin the inclusion bodies may be differentiated into three types. One type is derived from fat, another type from changes in the axons and fibrils, and the third type is formed by nuclear excretion. Only the first two types are associated with amaurotic family idiocy, and only they can be considered as evidence of degenerative metabolic processes, while the third type is seen in infectious diseases.

Every ganglion cell has a functioning part, the fibrils, and a vegetative part, the cell plasma. In amaurotic family idiocy the fibrils remain for a long time intact, and the severe changes in the plasma may produce few clinical signs and symptoms. Only in diseases of longer duration, when the fibrils, too, become deranged, do we find corresponding severe clinical signs. The atonic asthenia is due to cholinergic and adrenergic factors, obviously the result of changes in the thymus and the adrenals. It is similar to the asthenia found in myasthenia and in Addison's disease. R. Grunfeld.

Paulo, A., Jr. Ophthalmopathies of tuberculous nature. *Arquivos Brasileiros de Oft.*, 1942, v. 5, June, pp. 101-117.

This is an inaugural address delivered in the Escola Paulista de Medicina. It reviews the general subject of ocular tuberculosis, with numerous references to the literature, and with special discussion of phlyctenulosis, hemorrhage into the vitreous, and the disease known as Boeck's sarcoid. Of the last condition the author cites an individual case, in a woman of 45 years. There were deep orbital pains on the right side, which were said to have existed since sudden loss of vision some time previously. The left eye had tem-

porary obcurations of vision, and showed a 50-percent loss of visual acuity. There were nodules in the eyelids, in the frontal region, in the ala of the nose, and in the right malar region. After a month of treatment with tuberculin, all the subcutaneous nodules underwent absorption. In the course of a year glaucoma developed in each eye, and antiglaucomatous sclerectomies were performed. The right eye retained its vision, but the left eye became entirely blind. W. H. Crisp.

18

HYGIENE, SOCIOLOGY, EDUCATION,
AND HISTORY

Belfort Mattos, W. Need for medical syndicalism among the oculists. *Arquivos Brasileiros de Oft.*, 1942, v. 5, June, pp. 137-141.

This address, delivered upon taking over the presidency of the Ophthalmological Society of São Paulo, Brazil, talks very frankly of the inadequacy of the economic status of ophthalmology in Brazil. In that country there are not more than 800 ophthalmologists for a population of about 40 million. Although the Brazilian law requires syndicalization (a sort of trade union development) of physicians, the ophthalmologists are said to make little use of this means of coördinated effort. The author complains that, in the very proper desire of obtaining a good clientele and good economic standing, the new oculist, like other young physicians, seeks the poorly remunerative work of so-called benefit societies, or of insurance companies, or sacrifices all his mornings to the advantage of those exploiters of medical services, the charity clinics. The young oculist argues that he is there to learn and practice, forgetting that in all professions the apprentice also is paid for his work.

Frequently he works for an older colleague. He begins to run hither and thither in an automobile bought on "easy payments", to appear in medical gatherings and take part in discussions and dinners, and competes for the post of junior helper to the junior assistant in a charitable institution, in order to be able to use that position as an advertisement at the head of his prescription blanks, which he gets printed by some drug concern. The oculist neglects the smaller communities, preferring to remain in the large cities.

These and many other things Belfort Mattos says in order to demonstrate that within the Ophthalmological Society of São Paulo, side by side with the study and development of Brazilian ophthalmology, ophthalmologists can and should strive for a better economic and social condition of their specialty.

Chance, Burton. A survey of the state of ophthalmology in Philadelphia at the time of the founding of the Section on Ophthalmology at the College of Physicians. *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1164-1170.

De Brito Conde, Herminio. Inaugural address of the course on ocular hygiene. *Arquivos Brasileiros de Oft.*, 1942, v. 5, June, pp. 117-130.

The author, who is General Secretary of the Brazilian National League for the Prevention of Blindness, delivered the opening address in a series organized by the Brazilian General Secretariat of Health and Assistance. He insists on the need for an ocular conscience, cites from the literature classical examples of the influence of visual disturbance upon the career of the individual (especially with regard to an author named Machado de Assis), and

supports the belief that continuous near work may induce or aggravate pathological ocular conditions.

Lowenfeld, Berhold. Partially seeing children in schools for the blind. *Outlook for the Blind*, 1942, v. 36, Dec., p. 287.

This article is a survey of the admission requirements of partially seeing children for admission into schools for the blind. Legal requirements with regard to amount of vision are given and also the amounts of vision actually recognized for admission into various schools. Questionnaires returned by the schools furnished the information.

In most states a definite specification in regard to the amount of vision is not included in the legal requirements for admission. In 88 percent of the schools it is found impossible to adhere to a strict definition of blindness in dealing with admissions. The author explains the factors which cause requirements to vary.

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Browman, L. G., and Ramsey, F. Embryology of microphthalmos in *rattus norvegicus*. *Arch. of Ophth.*, 1943, v. 30, Sept., pp. 338-351.

There are a number of influences which affect and arrest the eye in its embryonic growth: for example, mechanical injuries, or abnormal pressures; infections, toxicoses, vitamin or other nutritional deficiencies, metabolic and endocrine disturbances in the mother ante partum, and interference with the blood supply to the embryo or to the developing primordia. Certain abnormalities of the eye have been shown to be inherited.

In order to study the heredity, the authors started with a female rat with bilateral microphthalmos and mated her with a normal-eyed litter mate; one microphthalmic animal appeared. Brother-sister matings of this strain were continued in an attempt to increase the proportion of small-eyed animals.

The average percentage of microphthalmic rats increased from a low of 19

to over 85 in the seventh generation. It is of interest to note that no litter in which all animals had some degree of microphthalmos was observed until the seventh generation. In this generation 7 of 20 females produced litters in which all of the young exhibited some degree of microphthalmos. In the present investigation 22 sixth-generation microphthalmic females were used to obtain 51 embryos and fetuses.

The development of the normal eye in a series of embryos from the microphthalmic females was followed from the optic-vesicle stage to the stage just before delivery. A table of this development is given. Only two brain anomalies associated with microphthalmos were observed. Autopsy disclosed that the optic nerves were missing in 19 of 48 adult rats with apparently normal-sized eyes, and with no opacities or other abnormalities. The peculiar association of absence of the hyaloid artery with a well-developed annular blood supply probably accounts for the appearance of a normal eyeball without an optic nerve.

In none of the 10.5-to-12-day-old embryos studied did the optic vesicle and the optic cup reveal abnormalities. It would therefore seem that the critical

period in the formation of microphthalmos in this strain of rats is at the time of formation of the embryonic blood supply to the eye, namely, at 12 to 13 days. Other structures in the eye and orbit were also involved. (8 figures, 35 references.)

Ralph W. Danielson.

Gregory, P. W., Mead, S. W., and Regan, W. M. A congenital hereditary eye defect of cattle. *Jour. of Heredity*, 1943, v. 34, April, p. 125.

Inbreeding experiments with Jersey cows, designed to fix the factors for high milk and butterfat production, have brought out a recessive change in the form of a congenital type of cataract. This was found in pure-bred Jerseys at the University of California. The lenses were smaller than normal and were dislocated. Ophthalmologic studies made included microscopic sectioning of affected eyes.

Communications should reach the Editor by the twelfth of the month

MISCELLANEOUS

ARGENTINA. The Argentine Committee for the Prevention of Blindness and Trachoma has appointed the following physicians to the Board of Directors for 1943-1944: Dr. J. Lijo Pavia, president; Pio Pandolfo, first vice-president; Enrique Monchet, second vice-president; Carlos R. Porto, treasurer; Dudley S. Drabble and Buido S. Longoni, secretaries.

The Argentine Ophthalmological Society held a theoretical-practical course on strabismus under the supervision of Dr. Jorge Malbran. The course consisted of a series of five lectures held at the Argentine Medical Association and three surgical demonstrations held in the Santa Lucia Ophthalmic Hospital. The subjects included in the course were: Mechanics of ocular movements; Binocular vision; Fusion; Disturbances of muscular equilibrium; Latent strabismus or heterophorias; Vision of the patient with strabismus; Etiopathogeny of strabismus; Convergent and divergent strabismus; Oblique strabismus; Treatment of strabismus; Paralysis of the extrinsic muscles of the eye; Paralysis of the third pair of supranuclear paralyzes.

BRAZIL. The Ophthalmic Board of Examination in Brazil (Consellio Nacional de Oftalmologia) has awarded certificates of proficiency to nearly 150 physicians in all the territory of Brazil.

Permanent postgraduate course for ophthalmologists. After holding postgraduate courses for seven years which have been fairly well attended by physicians from São Paulo, the interior, and even from neighboring countries, the Ophthalmological Clinic of the Escola Paulista de Medicina instituted the first permanent postgraduate course for ophthalmologists in June of the year 1943. The course will be so arranged that students can begin practical ophthalmology after concluding their studies. The lectures will be given in the presence of patients in the large specialized centers, so that the student can take an active and immediate part in propedeutics and surgery, accompanied by theoretical explanations on diagnostic fundamentals and prognosis. Those who wish to take only part of the course may do so after arrangements have been made with the secretary. The course can be started by the student at any time, thus making it easier for visitors from the interior to make a profitable stay in São Paulo.

MEXICO CITY. The Hospital Infantil in Mexico City was opened to the public on May 29, 1943. This building is the second to be completed in the new Medical Center now under construction. The building is of concrete and has six floors, with a capacity of 550 beds for children of all ages, from newborn infants to children 14 years of age. There is an ophthalmologic department as well as departments of pediatrics, orthopedic surgery, and so forth. The unit will be used also as a teaching department for the medical school of the National University, and has lecture rooms, classrooms, and students' laboratories located in the building. The Hospital is under the direction of Dr. Federico Gomez, a prominent pediatrician, who has been interested for many years in the construction of a children's hospital in Mexico City.

In the September-October number of the Transactions of the American Academy of Ophthalmology and Otolaryngology, Dr. Harry S. Gradle has an article on the history of the Pan-American Congress of Ophthalmology since its inception in 1939 to the first meeting of the Congress in Cleveland, Ohio, on October 11 and 12, 1940. The meeting followed directly upon the close of the meetings of the Academy. The article ends with the enumeration of the 12 fellowships granted by the Kellogg Foundation, which in normal times will be allotted to the different countries as follows: Argentina, 4; Bolivia, 1; Brazil, 6; Chile, 2; Colombia, 1; Costa Rica, 2; Cuba, 2; Dominican Republic, 1; Ecuador, 1; El Salvador, 1; Guatemala, 2; Haiti, 1; Honduras, 2; Mexico, 2; Nicaragua, 1; Panama, 2; Paraguay, 1; Peru, 1; Puerto Rico, 1; Uruguay, 1; Venezuela, 1.

GUATEMALA. The Girl Guides help in the local sight-saving activities by teaching the Braille method and conducting a clinic for the blind. A free clinic, in charge of Dr. Pacheco Luna, is shortly to be opened in the Casa del Niño. The 800 children who attend that institution will have their eyes examined when they enter at the age of one year, and regularly thereafter until they leave at the age of seven years. Both of these institutions are supported by the International Association of Lions.

SOCIETIES

Second Pan-American Congress of Ophthalmology

mology, scheduled to be held in Montevideo, Uruguay, November 4 to 9, 1943, has been postponed on account of conditions entailed by the war until the year 1944.

Brazil. Two ophthalmological societies have renewed their Board of Directors for 1943-1944. The Ophthalmological and Otolaryngological Society of Rio Grande do Sul elected Dr. J. G. Valentim, president; Dr. G. Torres, vice-president; Dr. Alfredo Schermann, first secretary; and Dr. J. P. Correa Soares, treasurer.

The Brazilian Society of Ophthalmology, Rio de Janeiro. At the December, 1942, meeting of the Society, the following papers were presented: Myopia due to the use of sulfanilamide, by Prof. Paulo Pimentel; A case of retinal changes in tuberous sclerosis, by Dr. Edilberto Campos.

The São Paulo Ophthalmological Society. The following papers were presented at the February, 1943, meeting: Therapeutic suggestions in three cases of uveitis, by Dr. Candido da Silva; (1) Anti-infectious action of the sulfanilamide drugs on the eyeball, and (2) Epidemic kerato-conjunctivitis and its actual im-

portance, by Dr. Moacyr E. Alvaro.

Mexican Society of Ophthalmology and Otolaryngology. At the September, 1943, meeting of this Society the following papers were presented: The problem of pupillary occlusion and its treatment, by Dr. H. Fernandez Isassi; The treatment of cancer of the larynx, by Dr. L. Vaquero.

PERSONALS

A number of students from Latin America are now studying ophthalmology in the United States for periods of six months to one year. Those known to the editor are: In New York—Drs. Ed. Garduña of Mexico, now at the New York Eye and Ear Infirmary; Drs. Scapini of Costa Rica, Vasquez of Paraguay, and Olmos of Mexico, at the Eye Institute of Columbia University; and Dr. Silva, in Chicago, at Dr. Gifford's clinic.

Dr. Conrad Berens, secretary of the International Congress of Ophthalmology, has been appointed to two new posts: Professor of clinical ophthalmology at Columbia University's College of Physicians and Surgeons, and Civilian consultant in ophthalmology to the Office of the Air Surgeons.

DEATHS

Dr. Philip A. Delavan, Saint Paul, Minnesota, died September 12, 1943, aged 44 years.

Dr. Homer F. Wonders, Philadelphia, Pennsylvania, died August 27, 1943, aged 66 years.

Dr. Charles A. Wynn, Greensburg, Pennsylvania, died August 20, 1943, aged 74 years.

Dr. William B. Anderson, Brownwood, Texas, died July 6, 1943, aged 80 years.

Dr. William K. Foote, Omaha, Nebraska, died July 22, 1943, aged 72 years.

Dr. John J. Finerty, Derby, New York, died September 18, 1943, aged 77 years.

Dr. Charles H. McArthur, Rome, Georgia, died August 2, 1943, aged 47 years.

Dr. Walter S. Moyer, Sayre, Pennsylvania, died July 18, 1943, aged 70 years.

Dr. George H. Bell, New York, New York, died October 5, 1943, aged 77 years.

Dr. Francis G. Speidel, Washington, D.C., died August 30, 1943, aged 51 years.

Dr. Alexander W. Stirling, Baldwin, Georgia, died August 16, 1943, aged 85 years.

Dr. Walter W. Watson, Philadelphia, Pennsylvania, died August 13, 1943, aged 69 years.

Dr. Wilston Johnston, Portland, Oregon, died August 15, 1943, aged 52 years.

Dr. Omar L. Cox, Iola, Kansas, died August 22, 1943, aged 76 years.

Dr. Melvin K. Henry, Philadelphia, Pennsylvania, died August 5, 1943, aged 72 years.

Dr. Frederick H. Martin, Libertyville, Illinois, died August 18, 1943, aged 71 years.

Dr. Edwin S. Moss, Williamsburg, Kentucky, died August 23, 1943, aged 83 years.

Dr. George H. Walker, Winona, Minnesota, died July 2, 1943, aged 63 years.

Dr. John J. Brennan, Worcester, Massachusetts, died August 26, 1943, aged 79 years.

Dr. A. W. Martin, Bogalusa, Louisiana, died October 6, 1943, aged 61 years.

Dr. Frederick W. Mitchell, Houlton, Maine, died September 5, 1943, aged 69 years.

Dr. Simeon A. Daudelin, Worcester, Massachusetts, died August 28, 1943, aged 73 years.

Dr. Carl Barck, Saint Louis, Missouri, died October 2, 1943, aged 86 years.

Dr. Benjamin J. Butler, East Providence, Rhode Island, died September 18, 1943, aged 69 years.

Dr. George R. Gowen, Walla Walla, Washington, died September 2, 1943, aged 61 years.

Dr. Ellwood Harlow, New York, New York, died September 22, 1943, aged 70 years.

Dr. Frank J. Walz, Wilkinsburg, Pennsylvania, died August 2, 1943, aged 72 years.

Dr. Thomas A. Poole, Washington, D.C., died October 5, 1943, aged 72 years.

Dr. Ernst G. Sass, Lidgerwood, North Dakota, died September 15, 1943, aged 73 years.

Dr. Otis F. Simonds, Cleveland, Ohio, died September 26, 1943, aged 61 years.

Dr. David F. Waide, New Orleans, Louisiana, died September 14, 1943, aged 60 years.

Dr. Edwin W. Grubb, Akron, Ohio, died September 23, 1943, aged 73 years.

Dr. Albert J. Gueriot, Pittsburgh, Pennsylvania, died September 18, 1943, aged 66 years.

Dr. Edwin S. Leach, Junction City, Kansas, died September 15, 1943, aged 76 years.

Dr. John M. McGrath, Saint Louis, Missouri, died September 21, 1943, aged 48 years.

Dr. Joseph E. Miller, Los Angeles, California, died September 13, 1943, aged 54 years.

Dr. Samuel J. Ottinger, Philadelphia, Pennsylvania, died September 15, 1943, aged 80 years.

Dr. James L. Rogers, Spokane, Washington, died September 3, 1943, aged 65 years.

MISCELLANEOUS

The Rochester Orthoptic Center (approved by the Monroe County Medical Society) offers a course for orthoptic technicians. Young women desirous of making orthoptics a career and of preparing for the examinations of the American Orthoptic Council may get full particulars from Mrs. Margaret Lundean, Orthoptic Technician, 31 North Goodman Street, Rochester, New York.

The McMillan Hospital was opened for eye, ear, nose, and throat patients on October 15th. This is the only specialty hospital for diseases of these organs in Saint Louis. The present capacity is 105 beds. Two additional floors are to be used at present for neuro-psychiatric patients. These contain 55 beds. This space may be available in the future for ophthalmic and otolaryngologic patients if it is needed.

The first floor and the basement of the building have been occupied by the ophthalmology and otolaryngology departments, respectively, for 13 years. The second floor contains four operating rooms and one large lecture room. The 3d and 4th floors are now used for neuro-psychiatry and the 5th, 6th, and 7th floors for eye, ear, nose, and throat. The six floors above these are for research laboratories of the Oscar Johnson Institute, internes' quarters, occupational therapy, squash courts, and offices of departmental chiefs.

The fifth floor is the ward floor of 49 beds. There are one 10-bed division, two 7-bed, two 6-bed, one 5-bed, and four 2-bed rooms for semi-private patients. The sixth floor is for

The McMillan Hospital and the Oscar Johnson Institute.

semi-private patients and the seventh for full private patients.

The Gill Memorial Eye, Ear, and Throat Hospital will hold its eighteenth annual spring graduate course in ophthalmology and otolaryngology beginning April 3, 1944. The following will participate in the program: Drs. Paul Holinger, A. C. Hilding, M. H. Lurie, Beverly Douglas, A. D. Ruedemann, Harold Falls, Raymond Ingalls, Milton Berliner, David G. Cogan, Paul Chandler, Eugene Blake, J. S. Shipman, Major Jerome Hauser, Admiral Ross T. McIntire, and Surgeon-General Thomas Par-ran.

The next examination held by the American

Board of Ophthalmology will be April 1, 1944, in Chicago.

The Department of Ophthalmology, George Washington University School of Medicine, held its semiannual meeting on December 4th presenting the following program: "Anomalies of the discs" by Drs. William T. Davis and Ernest A. W. Sheppard; "Pemphigus conjunctivae" by Dr. Edgar L. Goodman; "Bilateral amblyopia following crushed chest" by Dr. Ronald A. Cox; "Retinal detachment in childhood" by Dr. Frank D. Costenbader; "Foreign body in cataractous lens located by Vogt X-ray technique" by Dr. Richard W. Wilkinson; "Melanoma of the choroid" by Dr. Sterling Bockoven; and "Hypertensive retinopathy" by Dr. Carmon R. Naples. Colonel Frederic H. Thorne (MC), U.S.A., spoke on "Military aspects of ophthalmology," and Dr. Davis, professor of ophthalmology at the medical school, gave an illustrated lecture on "Differential diagnosis of the vertical motor anomalies."

SOCIETIES

At the eighth annual meeting of the Industrial Hygiene Foundation held at the Mellon Institute, November 10th and 11th, Dr. Charles F. Kutscher, Pittsburgh, spoke on "How the inhalation of some chemicals affects the eye."

The first of a series of postgraduate conferences, held by the eye section of the Philadelphia County Medical Society on November 4th, consisted of a discussion of "The diagnosis of corneal diseases" by Dr. Alfred Cowan and a paper on "Practical points in the refraction of the eye" by Dr. Sidney L. Olsho. The following ophthalmologists will participate in the series: Wilfred E. Fry, Isaac S. Tassman, George F. J. Kelly, Edmund B. Spaeth, Walter I. Lillie, James S. Shipman, Francis H. Adler, and Louis Lehrfeld.

The twenty-sixth meeting the Reading Eye, Ear, Nose, and Throat Society was held Wednesday, November 17, 1943. Dr. Warren S. Reese of Philadelphia read a paper on "Remarks concerning ophthalmic surgery." It was announced that Dr. Pearl E. Hackman had been commissioned Surgeon Reserve in the U. S. Public Health Service. Her rank is equivalent to that of a Lieutenant Commander in the Navy.

The regular meeting of the Washington, D.C., Ophthalmological Society was held on November 15, 1943. The guest speaker was Dr. James S. Shipman of Wills Eye Hospital, Philadelphia, who discussed "Treatment of retinal detachment." Case reports on "An unusual case of corneal dystrophy" and "Subconjunctival dislocation of the lens" were presented by Dr. Joseph Dessoff and Dr. J. B. Peebles, respectively.

The new officers of the Society are Dr. Sterling Bockoven, president; Dr. Harold R. Downey, vice-president; and Dr. John R. Lloyd, secretary-treasurer.

The Ophthalmological Society of Egypt, to encourage scientific ophthalmic work, has offered the grant of a prize, the ophthalmic gold medal, for the most valuable contribution brought up before the Annual Congress of the Society, according to a recent bulletin from the headquarters in Cairo.

PERSONALS

Dr. Daniel B. Kirby, professor of ophthalmology, New York University, was guest speaker at the October meeting of the Cleveland Ophthalmological Club. His subject was "Cataract surgery" and the lecture was illustrated with beautiful lantern slides and movies.

Dr. Michel Loutfallah announces the opening of offices for the practice of ophthalmology at 1826 State Street, Santa Barbara, California.

Drs. H. Rommel Hildreth and Carl C. Beisbarth were recently promoted to assistant professors of ophthalmology at the Washington University School of Medicine, Saint Louis.

Dr. Peter C. Kronfeld was appointed associate professor of ophthalmology at the University of Illinois College of Medicine, and also director of education (eye) in the Illinois Eye and Ear Infirmary.

Western Reserve University School of Medicine, Cleveland, celebrated its one hundredth anniversary the week of October 24th. Among the guest speakers was Dr. Daniel B. Kirby who presented a paper on "One hundred years of progress in cataract surgery."

TARSOCONJUNCTIVAL SLIDING-GRAFT TECHNIQUES FOR EYELID RECONSTRUCTION*

H. SAUL SUGAR, MAJ. (MC), A.U.S.
Vancouver, Washington

Since the introduction of Hughes's¹ method for reconstruction of the lower lid, it has been the most frequently employed method for defects involving the entire lower lid. In partial defects involving both skin and conjunctival surfaces, and under certain circumstances in complete defects, some of the other lid-splitting methods may, however, be more advantageous. These methods have therefore been assembled and briefly described. Included among them are the special techniques used in two types of cases by the author (figs. 8 and 11). These techniques may be of particular value in war injuries in which lid lesions frequently involve both skin and conjunctival surfaces.

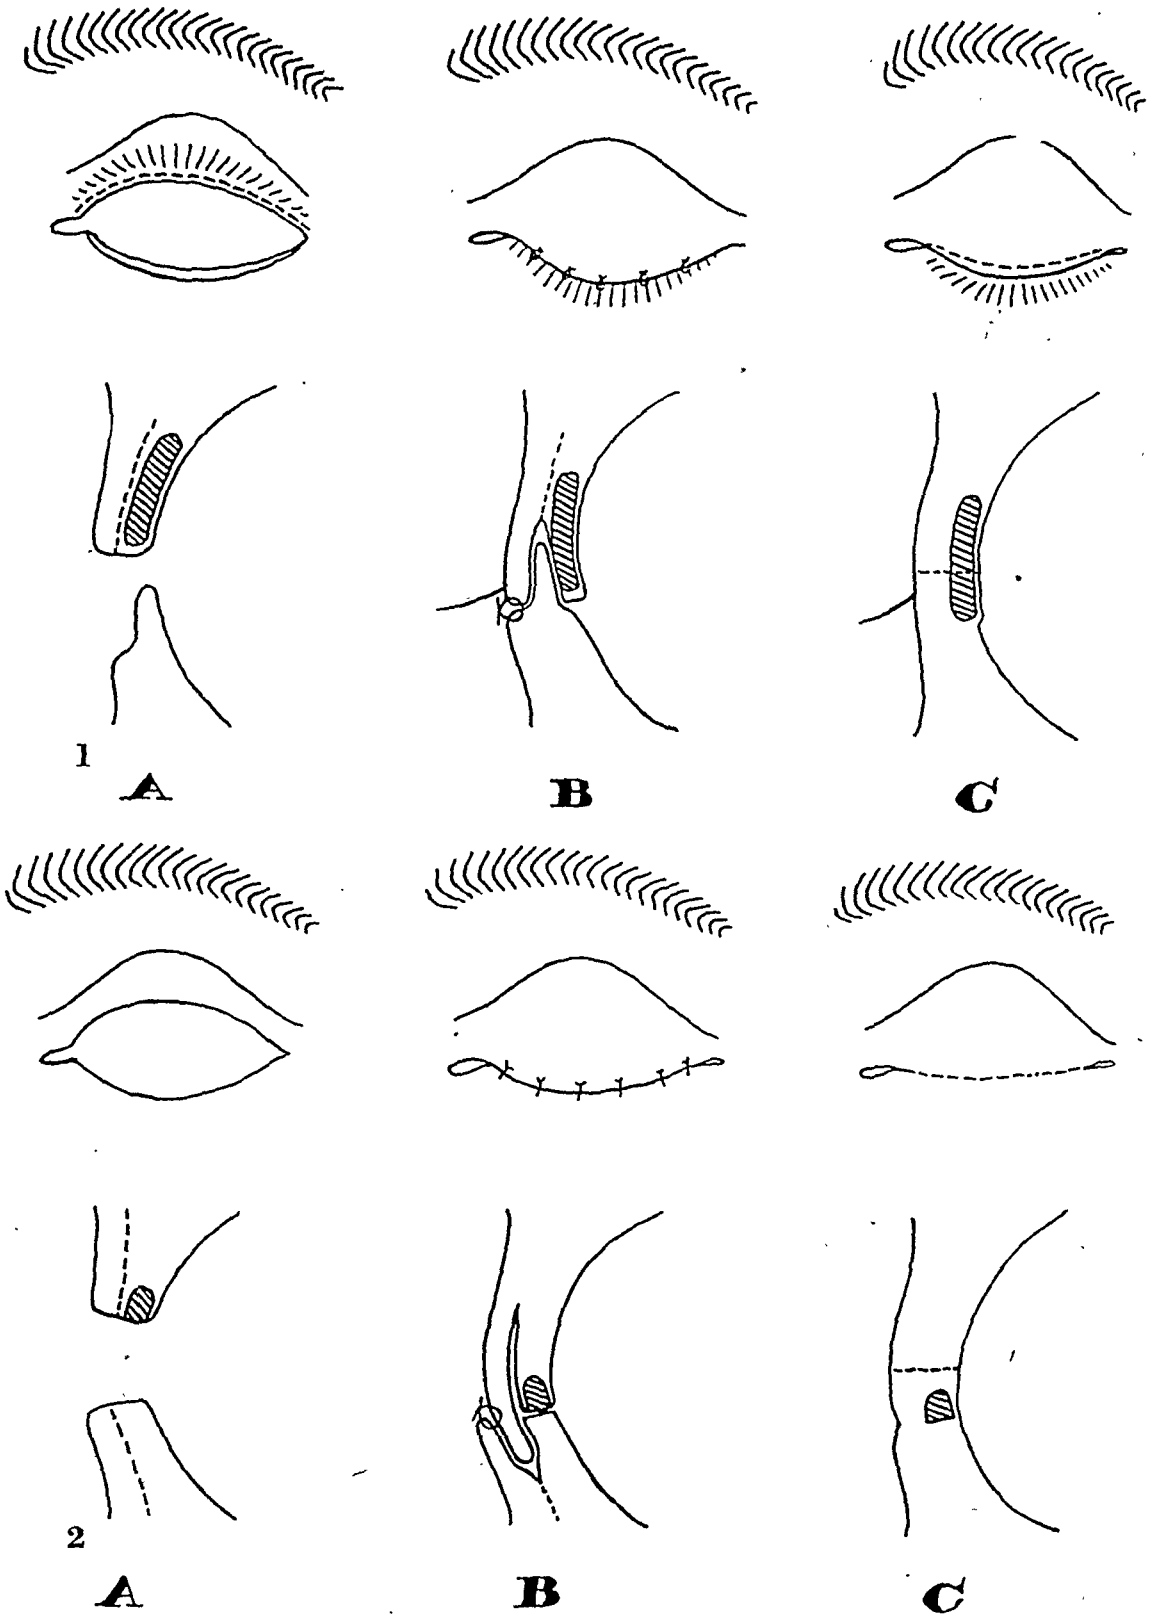

The first lid-splitting technique for eyelid reconstruction was introduced by Landolt² in 1881. This method was used to obtain skin to cover defects in the lower lid in cases in which part of the conjunctiva remained. The upper lid was split into a tarsoconjunctival layer and a skin-orbicularis layer and the free borders freshened (fig. 1). The conjunctival layer remaining in the lower lid was inserted between the two layers of the upper lid, and the skin of the upper lid was sutured to the skin edge of the defect. Later the tissues were split to form two lids. Four years later Landolt³ described

a method (fig. 2) whereby lids were reconstructed in a case in which only half of the upper lid remained. The upper-lid remnant was split and the marginal cutaneous surface freed of epithelium. The edge of the lower lid remnant was split and the skin layer of the upper lid inserted between the two layers of the lower lid and sutured. Later the tissues were split to form two lids. No cilia were transplanted.

A second useful lid-splitting technique for partial lower-lid reconstruction was introduced by Köllner⁴ in 1911. By this method (fig. 3), the upper lid is everted and an incision made through the conjunctiva and tarsus 2 mm. from, and parallel to, the lid margin, and sufficiently long to correspond to the defect in the lower lid. At both ends of the incision a vertical incision is made through the conjunctiva and tarsus, extending upward toward the fornix. This tarsoconjunctival flap is undermined, pulled down, and sutured in place in the lower-lid defect. The skin defect in the lower lid is filled with either a free or pedicle graft. Temporary lid-margin sutures are placed on either side of the defect area.

Kuhnt's automarginoplastic operation⁵ is another procedure which may be extremely useful, particularly in cases of tumor of the lid-margin. The skin around the mass is incised in the form of an arch (fig. 4). On the conjunctival surface two incisions are made through con-

* From the Eye Clinic, Barnes General Hospital (U. S. Army).

junctiva and tarsus perpendicular to the lid margin, beginning at the margin of the lid and extending in the conjunctiva to 1 cm. beyond the tarsus. Another incision is made parallel to the lid margin beyond the growth. The conjunctivo-tarsal flap thus prepared is brought toward the lid margin to fill the gap. The skin border is brought up and sutured temporarily

rim. This strip of tarsoconjunctiva is split into two flaps at a point which will permit the one on the side of the defect to approximate the conjunctival defect in the upper lid. This is rotated into position in the upper-lid defect and sutured to the upper-lid tarsoconjunctival flap. The remaining tarsoconjunctival flap of the lower lid is stretched to fill the tarso-

Fig. 4 (Sugar). Kuhnt's automarginoplastic operation. A, skin and tarsoconjunctival incisions; B, result of the repair.

to the upper-lid margin to fill the skin portion of the defect.

For partial defects of the upper lid Smith⁶ described the following procedure (fig. 5): An incision is made, splitting the remaining portion of the upper lid and the intact lower lid. An incision parallel to the margin is made in the two layers of the upper-lid remnant at the level of the upper orbital rim. A similar incision is made in the tarsoconjunctival layer of the lower lid at the level of the lower orbital

conjunctival defect in the lower lid, resulting from the rotation of the other tarsoconjunctival flap, and sutured into place. This leaves only the skin defect in the upper lid to be corrected. The skin flap formed from the upper-lid remnant is drawn over as far as possible and fixed to a flap made in the skin on the other side of the defect.

A fourth lid-splitting operation is that of Dupuy-Dutemps,⁷ described in 1927. It may be used for either partial or total

loss of the lower lid and in partial loss of the upper lid. In the first stage of this operation, if done for correction of a lower-lid defect, an incision, slightly longer than the defect to be filled, is made in the intermarginal line of the upper lid (fig. 6). The skin-orbicularis layer is separated from the tarsoconjunctival layer. The latter is sutured to the conjunctival edge of the lower-lid stump.

palpebral opening is reestablished by a through-and-through incision along the ciliary border.

The Hughes¹ operation for lower-lid reconstruction was described in 1937. By this method (fig. 7), the upper lid is split along the intermarginal line to about 3 mm. above the upper tarsal border. The skin of the cheek is undermined. The epithelium at the free border of the tarso-

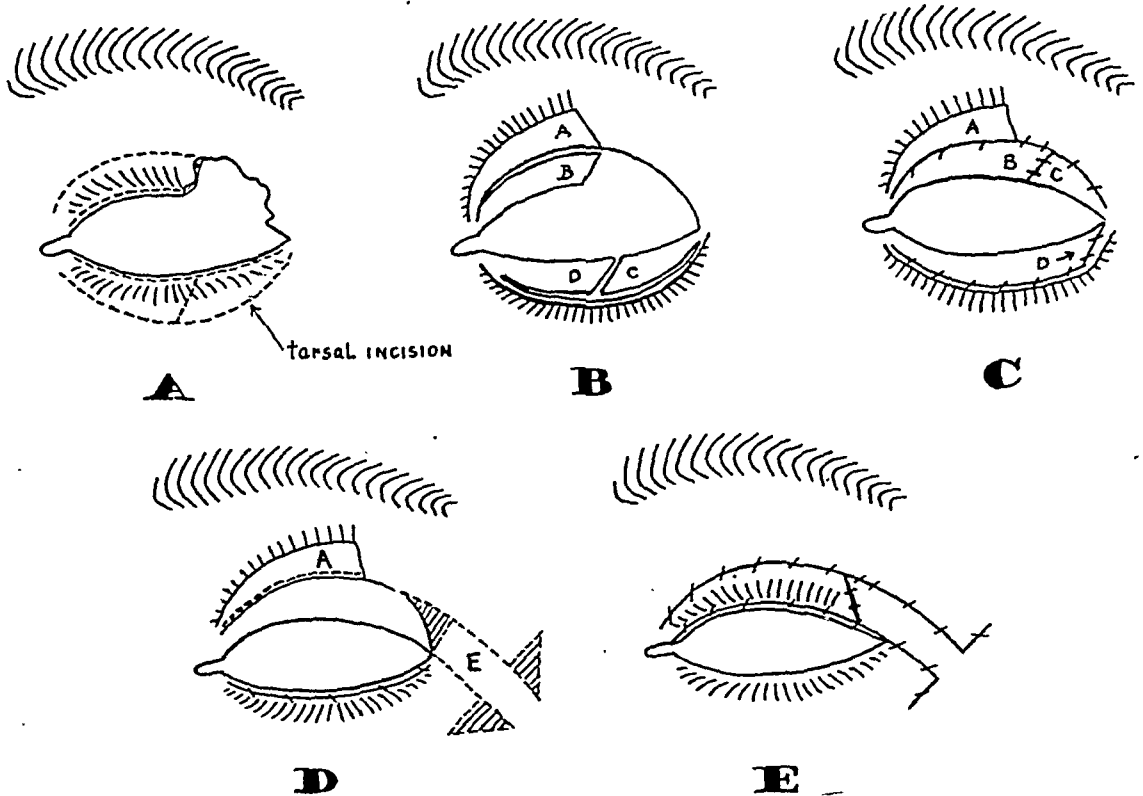

Fig. 5 (Sugar). Method described by Ferris Smith. A, outline of incisions; B, skin and tarsoconjunctival flap; C, rotation and suture of the flap C to edge of flap B—flap D is pulled over and sutured to fill the defect resulting from rotation of flap C; D, sliding flap E is formed to meet sliding flap A; E, the result of the surface repair. (After Smith.)

The skin-muscle layer is drawn downward and sutured to the skin borders of the lower-lid defect. After two weeks the second stage is done: The skin is incised just beneath the ciliary border and dissected upward so that the skin-muscle layer resumes its normal position, leaving the tarsoconjunctival layer in its new position. The skin defect is covered with a graft. Later, in two to four weeks, the

conjunctival layer of the upper lid is removed and the edge sutured to the conjunctival margin remaining in the lower fornix. The knots are left on the conjunctival surface. The skin of the cheek is drawn upward and attached to the anterior surface of the lower half of the tarsus. The skin-orbicularis layer of the upper lid is sutured to the anterior surface of the upper half of the tarsus. A

Fig. 8 (Sugar). Author's case 1. A, outline of incisions; B, result of surface repair, first stage; C, hair-bearing-graft implant; D, lid-separation stage.

subcuticular stitch is used to unite the two skin edges. At the end of six weeks a strip of hair-bearing skin is transplanted from the opposite brow to form the lower lashes, according to the method of Wheeler.⁸ After another seven weeks an incision is made transversely between the two rows of lashes to form the interpalpebral fissure.

Gifford⁹ has pointed out the need for leaving openings at both the inner and the outer canthi for drainage, instead of a single opening as in Hughes's procedure. He also considered the intermarginal subcuticular suture unnecessary.

Another lid-splitting operation somewhat similar to those of Dupuy-Dutemps and Hughes is that apparently used by Imre and Blaskovics and mentioned briefly by Saint Martin.¹⁰ According to this method the upper lid is split and the skin of the cheek and lower-lid remnant undermined. Imre's sliding flaps are formed by curved incisions as indicated in each individual case. Burow's cutaneous triangles are removed at the ends of these incisions as necessary. Such a procedure was used by the author in cases of partial loss of the lower lid resulting from a war injury, with very satisfactory results (figs. 8, 9).

CASE HISTORIES

Case 1. Lt. V. F. P., aged 28 years, was injured by enemy gun fire June 4, 1942, when the plane in which he was the bombardier attacked a Japanese ship off Umanak, Alaska. An enemy shell exploded in the nose of the plane. A secondary missile lacerated the patient's left eye and left lower eyelid. Lacerations of the skin of the nose, left angle of the mouth, and the left forearm were also incurred. On the following day an enucleation of the remnants of the left eye was done. The fragments of the lower lid that were present were sutured into position, al-

though some of them were in such condition as to make their viability questionable. On June 12, 1942, the patient was evacuated to Barnes General Hospital. The sutured lid remnants had sloughed out and some deformity of the external

Fig. 9 (Sugar). Appearance of patient (case 1) before and after surgery. A prosthesis was inserted before photographing.

canthus was present. The lateral two thirds of the lower lid were absent to the lower fornix. Because of a desire to preserve the lacrimal punctum and the normal lid remnant the following procedure was done on June 18, 1942: The skin of the left cheek was incised and undermined as shown in figure 8. A

Burow's triangle was removed at the end of each lateral curved incision. The more nasal skin incision was made nasal to the edge of the tarsal remnant so as to give the effect of Wheeler's "halving" operation. The upper lid was then split into a tarsoconjunctival and a skin-orbicularis layer, beginning at the intermarginal line and extending to about 4 mm. above the upper tarsal border. The tarsus was incised vertically at the external canthus and at the junction of the inner and middle thirds to fill the defect in the lower lid. A prosthesis was inserted to give the lids form. The free edge of the tarsal layer was denuded of epithelium and sutured to the conjunctiva of the lower fornix, leaving the knots on the conjunctival side. The skin of the cheek was brought up and sutured with three vertical silk sutures to the lower half of the tarsus. A subcuticular suture was placed between the two cutaneous edges. A thin rubber drain was inserted at the inner canthus and at the lacerated outer canthus. The cilia were held up with collodion. A pressure dressing was applied. On the sixth postoperative day the dressing and sutures were removed. A small epithelial defect in the upper outer corner of the graft was present. Two attempts to place a small free partial-thickness skin graft over the area were unsuccessful because of the constant secretion from the opening at the outer canthus. The defect healed well of its own accord, however. On August 2, 1942, a horizontal incision was made just below the intermarginal adhesion, extending down to the tarsus. A wedge-shaped hair-bearing graft $1\frac{1}{2}$ mm. wide at the skin surface was removed from the right brow. This was turned end for end and inserted into the trough in the left lower lid and sutured into place. The brow incision was closed with interrupted sutures. A pressure bandage was applied

to the left lids. On September 15th, a through-and-through incision was made at the lower border of the left upper lid. The prosthesis was removed. The conjunctival sutures and granulation tissue were removed, the prosthesis reinserted, and a dressing applied. Healing was uneventful.

Case 2. Lt. R. K. U., aged 23 years, received multiple shrapnel wounds from 20-mm. cannon fire on September 11, 1943, while serving as co-pilot on a bombing mission over Paramushiro. One fragment, 2 by 0.5 by 1 cm. in size, passed through the right eyeball and entered the right posterior inferior ethmoid sinus. The lateral third of the right lower lid was excised by a piece of plexiglass from the windshield. The eye was eviscerated on September 13, 1943. On October 26, 1943, the patient was admitted to Barnes General Hospital. The conjunctiva was continuous with the skin where the lateral third of the right lower lid was missing. The conjunctiva was clean but considerably shortened. On November 1, 1943, the lateral third of the upper lid was split, and the tarsoconjunctival layer sutured to the freshened conjunctival margin of the lower-lid defect exactly as was done in case 1. The skin of the cheek was incised and sutured to the lower half of the tarsus as in case 1. No prosthesis could be inserted as a mold. On the sixth postoperative day the dressing and sutures were removed. On November 22, 1943, a hair-bearing graft, 12 mm. in length, from the left brow was inserted into an incision in the new lower lid, as in case 1. Three weeks later the lids were split. Because of the lack of sufficient conjunctiva to permit insertion of a prosthesis, the temporal half of the conjunctiva was split on December 23, 1943, and undermined to permit insertion of a mold and a mucous-membrane graft from the lower lip. A mold of the same size and

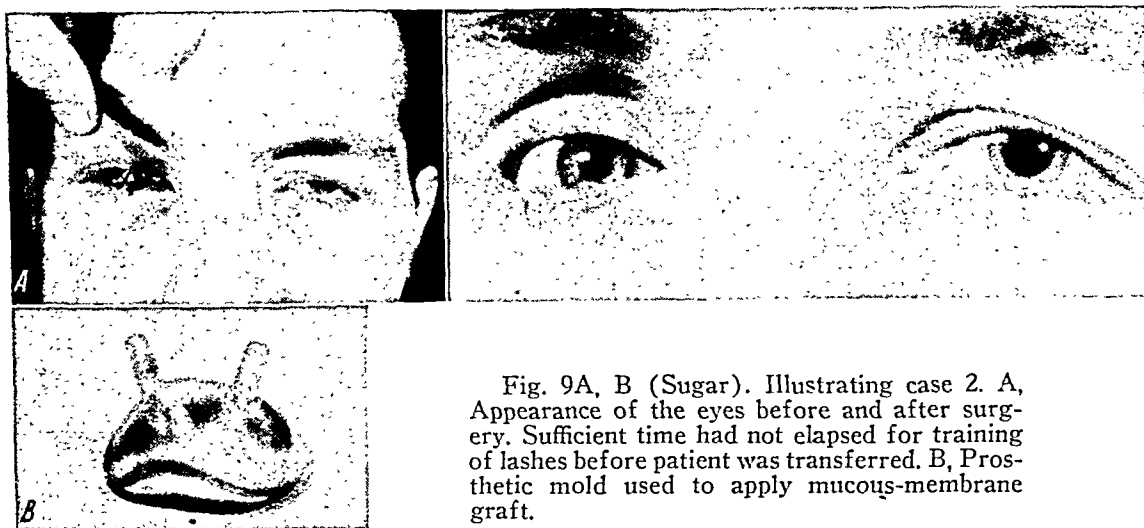

Fig. 9A, B (Sugar). Illustrating case 2. A, Appearance of the eyes before and after surgery. Sufficient time had not elapsed for training of lashes before patient was transferred. B, Prosthetic mold used to apply mucous-membrane graft.

shape as an artificial eye was made of transparent acrylic by Capt. E. V. Lambrechts of the Dental Department, according to the description by Penn and Brown,¹¹ except that, instead of perforating the mold with steel tubes to drain secretions accumulated behind the mold, perforated extensions continuous with the rest of the acrylic mold were used (fig. 9A, B). The mold was removed in five days, leaving a clean, well-grafted socket. A temporary artificial eye was introduced three days later preparatory to transfer of the patient to a center where a proper prosthesis could be made.

The procedure used in these cases embodies several important principles of lid reconstruction including: 1, lid-splitting; 2, the use of the Imre sliding flap with Burow's triangles; 3, the Wheeler hair-bearing-graft transplant to form lashes; and, 4, the Wheeler¹² principle of "halving" whereby the skin and tarsoconjunctival layers are united at different levels to minimize scar contraction.

As a result of the experience with these cases I am convinced that tying the sutures which unite the conjunctival layers on the conjunctival side introduces a source of irritation. It is possible in a case in which the globe is intact that a serious corneal ulceration may result. It

might be wiser to place the sutures from the skin side and tie them after passing them through the undermined skin of the cheek at the proper level. Not only would they then permit earlier removal of the suture material but would serve instead of the vertical tarsus-skin sutures to hold the graft up to relieve tension.

A lid-splitting method for reconstruction of the upper lid for carcinoma was described by McLean¹³ in 1941. By this method (fig. 10) two incisions are made through and through the normal tissue on each side of the growth perpendicular to the lid margin, and another parallel to the lid margin, delimiting the involved tissue. At each corner a Burow's cutaneous triangle is removed. The levator muscle is isolated and secured. The lower lid is split and the tarsoconjunctival layer attached to the conjunctival edge of the upper-lid defect after its edge has been freshened. An orbicularis strip from the upper lid is swung down over the transplanted tarsus. The skin above the defect is drawn down and sutured to the edge of the skin layer of the lower lid. Later a hair-bearing graft is inserted, according to Wheeler's method. As a final stage the lids are split.

For contiguous lesions of both lids

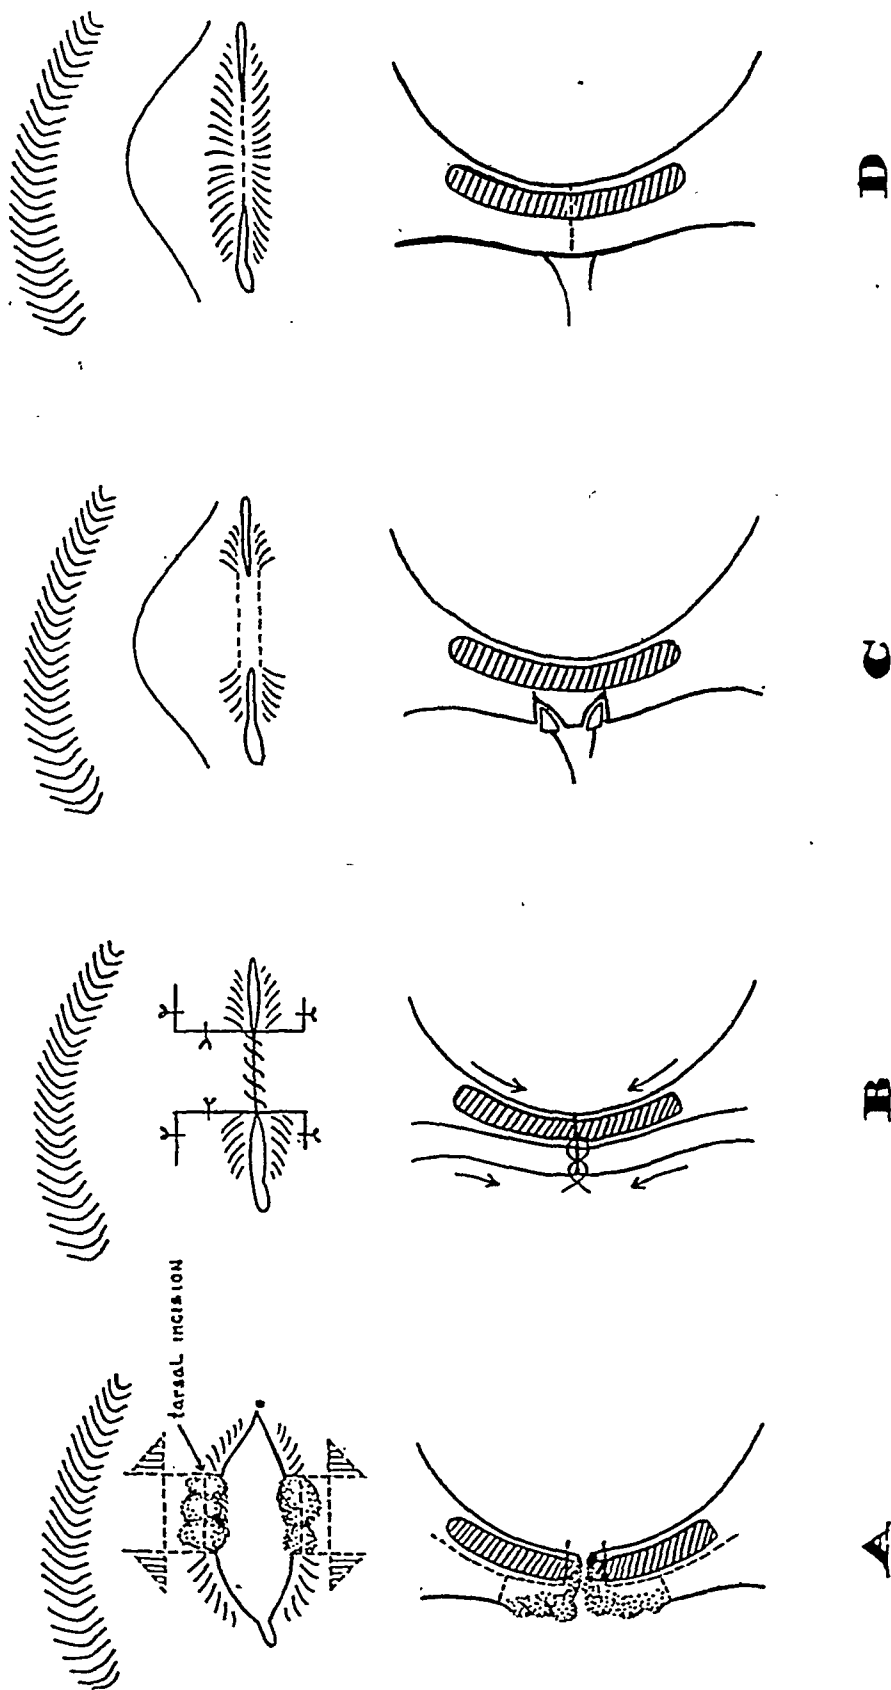

Fig. 11 (Sugar). Author's case 2. A, outline of incisions; B, result of repair; C, hair-bearing-graft implants; D, lid-separation stage.

I have used a method (fig. 11) described in the following case history:

Case 3. Pvt. R. O. B., aged 27 years, was admitted to Barnes General Hospital on April 8, 1943, because of inability completely to close his right eye owing to the presence of contiguous growths on the margins of both right lids. The upper mass had been present since birth, the lower was first noted at the age of 12 years; both had grown moderately in size. The upper mass measured 14 by 6 mm., whereas the lower measured 6 by 12 mm. in size. Both extended about $1\frac{1}{2}$ mm. on the conjunctival surface. The pathologist's diagnosis was papillary pigmented intradermal nevi.

On April 13, 1943, the skin was incised as shown in figure 11, in the same manner as followed in making McLean's skin incisions except that only a small border of normal skin was included. Burow's triangles were removed from the four corners. The skin was undermined beyond the excised areas. The tumor masses were removed, leaving the tarsoconjunctival layer intact except for $1\frac{1}{2}$ mm. at its free border on each lid. The tarsi were incised at the lateral margins of the defects without going through the conjunctiva so that the tarsal margins could be sutured together without leaving a gap between them. The sutures were brought out through the flap edges and tied. The skin edges were then united with interrupted sutures. The sutures were removed on the fifth postoperative day. On April 27, 1943, horizontal incisions were made just above and below the intermarginal adhesion, extending along the tarsus above and below. Thin hair-bearing grafts were removed from the left brow and sutured into place in the troughs. The brow incision was closed with interrupted sutures. The sutures were removed on May 1st, at which time collodion was used to direct the hairs into the proper posi-

tion. On May 12, 1943, the lids were separated. Healing was uneventful.

This procedure was planned as a combination of the methods of Köllner and McLean. However, only a small amount of tarsus was found to be involved. In cases presenting more involvement of the tarsus, a through-and-through vertical incision of the tarsus and tarsal conjunctiva should be made on each side of the

Fig. 12 (Sugar). Appearance of patient (case 3) before and after surgery.

lesion in each lid, either continuous with the cutaneous incisions or slightly away from them so as to produce the effect of "halving." The incisions should extend for 4 mm. or more in the conjunctiva and a tarsoconjunctival or conjunctival flap formed by undermining. The conjunctival or tarsoconjunctival flaps from

the two lids should then be united by sutures that are continued through the cutaneous flap margins and through small pieces of rubber over which they are tied.

It will be noted that in both procedures used by the author the same four principles were considered and may be applied in any case where tarsoconjunctival sliding grafts are used. These are, in recapitulation: (1) splitting the lid into tar-

soconjunctival and skin-muscle layers; (2) use of Imre sliding skin flaps with Burow's triangles, where indicated; (3) use of the Wheeler method for forming lashes; and (4) use of the Wheeler "halving" principle, where applicable. These principles may be applied in the repair of lid colobomas, traumatic defects, and the defects resulting from the removal of tumors.

THE DEVELOPMENT OF A SYSTEM OF INTRACAPSULAR CATARACT EXTRACTION

DANIEL B. KIRBY, M.D.
New York

In the descriptions of new procedures in intracapsular cataract surgery various authors have conveyed to the reader their particular techniques, but they have not given the variations and indications necessary to adapt the manipulations to the case in hand. They have not told what to do next, if a particular procedure fails to produce the desired result.

The present writer has made it a habit to examine patients and their eyes carefully, with all necessary devices, before operating and then to continue his observations before and after each maneuver during the operation. He has looked and has seen what he has accomplished before he has proceeded to the next maneuver. Manipulations have been varied according to indications as they presented.¹ Gradually there has been developed a system of intracapsular cataract extraction, which may be defined as an orderly array of thoughts on this particular subject. When once the decision has been made to remove the cataract in capsule, the surgeon has a better chance of success if he has formulated in his own mind the procedures which he will apply under certain conditions and if he is prepared to vary them if the conditions change.

One cannot anticipate by age, physical condition, nor local examination of the eye, even with the microscope, just how the operation will proceed. If all of the possible contingencies, emergencies, or complications² have been encountered in practice or in teaching, and are anticipated, then the unexpected becomes the expected and is no surprise. One may then assay the situation more calmly and

proceed with a cold and scientific accuracy of thought and precision of application which leads the way out of disturbing situations and even out of complications that might be distressing.

The observations and procedures described in this paper have been developed in the course of private surgery, *not* with any idea of experimentation but because a previously or spontaneously developed idea seemed to fit a particular situation, was applied, and was then reapplied when a similar situation arose. Ward or clinic patients in the author's service were all operated upon by residents in their training in extracapsular or intracapsular surgery, as indicated in the particular case. No cases have been used for demonstration purposes.

THE BASIS OF THE SYSTEM

The exposition of the system of intracapsular cataract surgery in this paper will be chiefly concerned with the behavior of the lens capsule, cortex, nucleus, zonule, and vitreous. It is necessary to consider not only the cases with intact zonules in which there is apparently normal anatomic position of the lens and vitreous but also those in which there may be subluxation or luxation of the lens, either through congenital malformation, degeneration, or through trauma.

INTRACAPSULAR DELIVERY OF LUXATED AND SUBLUXATED LENSES

In all cases of subluxation or luxation the placement of efficient corneoscleral sutures prior to incision is indicated. In

congenital cases and in certain cases in which minor trauma caused luxation or subluxation of a cataract with a fragile zonule, the hyaloid may be intact and it may be possible to remove the lens without loss of vitreous; but in severe traumatic cases, the vitreous and the hyaloid are greatly disturbed and loss of vitreous is to be expected and prepared for. If the lens is completely free from its zonular attachments, the ligamentum hyaloidea capsulare may support the lens in position. In clinical surgery, in cases of cataract, there is little evidence that the ligamentum hyaloidea capsulare is any more than anatomic coaptation, except in rather rare pathologic instances where the hyaloid seems to be adherent to the posterior lens capsule. It is possible that in the normal eye there is a slight degree of cohesion and that this property is diminished when the ligament degenerates with the development of cataract.

Luxation of the lens into the anterior chamber. Differentiation of this condition in certain instances must be made from hematogenous staining of the cornea. Removal of the luxated lens in capsule from the anterior chamber is definitely indicated because if increased intraocular pressure has not already developed it will undoubtedly ensue. If the intraocular pressure is not elevated, a small peripheral incision, avoiding injury to the lens capsule, may be made with the knife and then enlarged with scissors. The lens may escape as soon as the incision is large enough or it may be withdrawn by traction with suitable forceps, suction cup, or with a loop.

Increased intraocular pressure in cases of luxated lenses. If the intraocular pressure is increased, the opening of the anterior segment is hazardous because of the crowding forward of various struc-

tures, and the danger of hemorrhage and of iris and vitreous prolapse. The writer has not made use of his plan as yet to lower the intraocular pressure, in cases of subluxated or luxated lenses, by drainage of the vitreous. He would do this, not by posterior scleral puncture with a knife but by a method which has worked well as a preliminary to an anterior operation in certain cases of glaucoma. After exposure of the sclera in the inferior temporal quadrant by conjunctival and Tenon's-capsule dissections, the sclera in an area 10 to 12 mm. posterior to the limbus is trephined to the choroid. The latter naturally bulges into the opening. Electro-coagulating current of intensity similar to that used in the operation for reattachment of the retina is used to pierce the choroid, then the retina, then the internal limiting membrane or hyaloid, whereupon the vitreous is permitted to escape slowly. The relations of the structures in the anterior segment then may appear more normal. Even though the initial limbus incision may be difficult in a decompressed eye, it seems to the author that this may prove to be a better way out of the emergency than a primary anterior drainage. This procedure is recorded here as an untried example of the preparation for an emergency in the development of the system of intracapsular cataract surgery. It is not recommended and it may be necessary to discard it, but it is nevertheless recorded for the sake of completeness.

Luxation of the lens with retention of its position in the patellar fossa. It is possible, although not probable, that the lens may remain in the patellar fossa even though completely free from the zonular attachments. The hyaloid must necessarily be intact for this condition. The lens may be removed by traction alone, with

the forceps, suction cup, or with the loop.

Luxation of the lens into the vitreous. This condition may develop as a result of malformation or degeneration of zonule and vitreous or because of trauma either accidental or during the process of cataract surgery. Except in the last-named instance, the position, movement, or fixation of the luxated lens should first be carefully studied with the ophthalmoscope and particularly with the aid of the phenomenon of fluorescence of the lens by suitable devices.

If the lens will come forward when the patient lies face down, it may settle into the anterior chamber through the dilated pupil and then be imprisoned by the action of miotics, later to be removed through an anterior incision. If one does not succeed in moving the lens in this manner, the procedure will then depend upon the question of whether the vitreous is abnormally fluid or normally viscid.

Luxation into fluid vitreous. If abnormally fluid, the seepage of fluid vitreous directly after the incision, with lowering of intravitreal pressure to that of the atmosphere, is expected. The procedure described by Verhoeff,³ of floating a lens that is not adherent up to the anterior region of the eye, where it may be picked up by forceps or by loop and removed, should be tried. If the lens is adherent to the internal limiting membrane or to a false membrane on the retina, the prognosis for removal and restoration of function is poor.

Luxation into viscid vitreous. If the lens is luxated into viscid vitreous, there seems to be no option but to use the loop. The application of forceps or suction tip to lens capsule through intervening vitreous is out of the question.

Toilet of the incision after loss of vitreous. A complete, wide iridectomy should have been made in preparation for loss of viscid vitreous, in cases of traumatic luxation of the lens, so that when the preplaced corneoscleral sutures are tied to close the incision effectively, there will be no iris incarceration. It is difficult to replace the iris pillars when viscid vitreous is in the incision. A miotic may be used to help keep the iris from becoming incarcerated. Any vitreous that protrudes should be cut off flush with the incision. Careful and unhurried closure of the incision will help in the healing of such eyes.

Subluxation of the lens. This may develop through congenital malformation, degeneration, or through trauma.

Congenital malformation with subluxation of the lens. The zonule may be incompletely formed and may be the cause of unilateral or bilateral, usually symmetrical, subluxation of the lens. The lens is small and spherical or nearly so. The hyaloid is usually intact and the vitreous self-contained, although this may not be true. If the vitreous and hyaloid are intact, an attempt should be made to remove the lens without loss of vitreous. This may be accomplished as in the experience of the author in the case of a woman, aged 52 years, who had an upward subluxation of the lens in the right eye. Preplaced appositional sutures of the McLean⁶ type were inserted. A preliminary iridectomy had been made by another surgeon. The author's plans in a similar case would be to perform only a peripheral iridotomy. Incision was made in the usual upper segment of the corneal limbus. The central suture was used to retract the corneal flap, giving a direct view of the lens capsule and permitting the blades of the intracapsular lens-cap-

sule forceps to be placed ever so lightly upon the capsule, to be closed, picking up a portion of the capsule, to draw the lens down so that the zonule was exposed. This permitted it to be stripped off the capsule with the aid of the rounded elbow of the author's lens-expressor hook. The lens was thus delivered without presentation or prolapse of vitreous. The sutures were tied. There was no incarceration of iris tissue, so that it was not necessary to use the iris repositor. A miotic was instilled. The final healing and result were satisfactory. The usual procedure in cases similar to that just described is to attempt to remove the lens with the loop.

The zonule of the young is resistant and elastic. Observations have been made in such cases in young individuals who have very elastic zonules which resisted several attempts to withdraw the lens, the latter eluding the loop when nearly out of the eye and springing back to its original position as if drawn there by a very live elastic band. It is not known whether such a zonule may be stripped off by the dull elbow of the lens-expressor hook. If not, a sharper zonulotome, such as an iris spatula, may be in readiness to divide such a zonule rather than permit the lens to escape from the loop. The repetition of the ineffective maneuver of traction alone in such a case is to be avoided.

Subluxation of the lens through trauma or degeneration associated with cataract formation. Careful examination should be made to determine, if possible, the portion of the zonule that is still intact and attached to the lens before the section is made. If this can be discovered, the incision may be placed so that the loop may be passed through the open area and not through the intact portion of the zonule; thus the danger of com-

pletely luxating the lens into the vitreous is avoided. In many instances the intact area is not apparent, and is discovered only after the section has been made. The expected loss of vitreous is to be anticipated with preplaced sutures and by iridectomy. Trauma that will subluxate the normal lens will surely disturb the vitreous greatly. If the intraocular pressure is increased, recourse may be had to posterior draining before the anterior incision is made, as described previously.

If the intact zonule is in the inferior position, the lens will tend to swing backward on the zonular hinge. It may be brought forward by the loop, which is passed behind it from above. If the intact zonule is on one side or the other, the loop may be rotated over the opposite equator of the lens to get behind the lens and bring it forward. If the intact zonule is above, a variation of the incision from the straight horizontal to one or the other oblique may be made. Then the loop may be passed and rotated over the equator of the lens. If the straight horizontal incision has already been made, it may be possible to use the loop in a similar manner or to clear the vitreous from the upper face of the anterior equatorial region and apply the suction cup, using no pressure. These manipulations have all been employed by the author. No one can be satisfied with the appearance of an eye after it has been subjected to a wide iridectomy and the apparent necessary and expected loss and incarceration of vitreous, in traumatic cases. The patient, however, may be considered fortunate to preserve any visual function at all after such severe injuries.

In cases of degeneration of the zonule with minor trauma, conditions may be such that vitreous loss need not be experienced in the removal of subluxated lenses.

INTRACAPSULAR CATARACT EXTRACTION IN EYES WITH INTACT ZONULES

The indications for intracapsular cataract extraction have been discussed frequently. The writer does not consider that there is any hard and fast rule in the matter. In general, unless there is a special sensitivity to the substance of the cataract, cases of mature senile cortical and of dense nuclear sclerosis may do as well with extracapsular as with intracapsular extraction, although the number of operations required to achieve the final visual result will be greater in the extracapsular group because of the discissions required should aftercataract develop. In cases of intumescent cataract in which the capsule is taut, and resists the application of the forceps, intracapsular extraction may be performed with pressure or traction alone, with a suction cup if the zonule is fragile; but if not, it is better that the capsule be opened and the extracapsular procedure employed or the cataract be permitted to progress to maturity and the choice of procedure deferred until then. The intracapsular procedure is the method of choice in cases of luxated and subluxated cataract; in hypermature cataract, either of the shrunken or Morgagnian type; in cataract complicating glaucoma either primary or secondary to inflammation, in cases of exfoliation of the lens capsule, uveitis, and retinitis pigmentosa. When the intraocular pressure is low, the intracapsular procedure may be used if the zonule is fragile, otherwise the extracapsular operation should be employed. If the decision has been made to remove the lens in capsule this should not be regarded as final and permitting no deviation because a mishap may turn the procedure into an extracapsular one should a tear in the capsule supervene. The surgeon may also decide after an effort that the risk is too

great and change over to the extracapsular procedure. However, any surgeon who elects to start an intracapsular extraction should be prepared to carry it through confidently to a successful conclusion with a minimum of trauma and complications and certainly without inflicting any greater trauma on the eye or causing any greater complications on the average than would be incurred if the extracapsular procedure were routinely used. Results speak for themselves and while surgeons like Weeks, Wheeler, and others have had most enviable records and a long history of success with the extracapsular operation, immediate and long-continued, beautiful results are obtained with the intracapsular method. The writer was trained in the extracapsular procedure and had 10 years of experience with it. Now he has had 10 years of experience with the intracapsular procedure. Because of the relatively infrequent inflammatory reaction, the low incidence of secondary rise of intraocular pressure and other complications, and the large percentage of cases in which it can be applied with as reasonable an expectation of success as the extracapsular, he has permanently adopted the intracapsular procedure, to be used when indicated.

The iris. The successful intracapsular extraction together with a completely mobile, round pupil offers the ideal result. The choice of the round pupil may be made in any case in which the pupil will dilate to 6 mm. or more. It may be made if the pupil dilates only to 5 mm., should the cataract be small. In case the iris is rigid and the pupil will not open to more than a diameter of 4 mm., a complete coloboma is necessary. In difficult cases and when it is impossible to get a peripheral grasp of the lens capsule at or near the equator, the coloboma of the com-

plete iridectomy facilitates the operation. A miotic is used after the successful intracapsular operation.

The zonule. The writer has found by clinical surgical experience that about 15 percent of the zonules are fragile, 70 percent have average resistance, and the balance have above the average resistance and resiliency.

There is no age group into which these three classes fall. One might expect resistant zonules in the younger group of cataract patients, and the weakest zonules in those over 60 years of age, but the conditions found do not permit such a classification—they undoubtedly vary in racial units. The early deterioration observed in certain of the Asiatic groups provided more fragile zonules than those found in the Caucasian groups. The normal healthy human zonule is undoubtedly very resistant and resilient. There is probably always some degree of degeneration of the zonule in every case of cataract.

METHODS AND PROCEDURES

A brief review of the history and of the methods and procedures devised by various surgeons was given in a previous article.¹ The author has developed a method of using pressure before the application of traction and rotation of the lens. He has used it with success in cases in which the zonule ruptures easily on slight pressure, and in those cases in which an average amount of pressure, traction, and rotation is necessary to cause rupture of the zonule and provide for delivery of the cataract. The preliminary pressure that is used to subluxate the cataractous lens is applied with the point of a hook (preferably not a heavy or blunt point but a flattened point, such as is found on the Jamison muscle hook). Point pressure (approximately

2.5 mm. by 0.5 mm.) is preferred to pressure with a ring or with the side of a lens spoon; for the point reaches down to the space between the corneal ring and the equator of the lens, whereas the broader instruments do not do so. The author has devised an intracapsular lens expressor, using the Jamison hook tip on his own 5-mm.-diameter light-weight cylindrical handle. The pressure is applied just inside the clear periphery of the cornea, the ring of the limbus being easily and distinctly felt. The principle involved in the confinement of pressure to this inside circumference of the cornea lies in the applied anatomic fact that the lens diameter (approximately 10 mm.) is less than that of the transparent cornea (approximately 11.5 to 12 mm.) and, therefore, the zonule attached to the equator of the lens is just inside the corneal periphery. The flattened point of the hook, as described, may be insinuated between the lens equator and corneal periphery, reaching the zonule through the thickness of cornea and iris. The point first pressed upon is at the 6-o'clock position on the corneal dial; next, another point is pressed upon at 8 o'clock, and then at 4 o'clock, a slight stripping movement being used, designed to slide down over the convexity of the inferior equator of the lens and release the zonular fibers from their attachment at the equator. The manipulations may be repeated once and possibly twice to achieve the result. As an alternate to point pressure, circumferential pressure in curvilinear fashion inside the ring of the limbus of the cornea may be applied, gradually covering almost all the lower semicircle of the limbus. The degree of pressure and indentation of the cornea varies in the individual case. In general, however, the pressure may be described as rather sudden and sharp, indenting the cornea 2 to 3 mm. but within the limits of what may

be regarded as safe. Indications of yielding and of rupture of the zonule and the movement of the lens, its tilting, and presentation when subluxated, must be learned by experience. It may be said that when the zonule has ruptured there is less resistance, and the body of the lens rises. It is never necessary, in an attempt to remove a cataract in capsule, to apply pressure over the white portion of the sclera, thus traumatizing the ciliary body and disturbing the vitreous body. The reasons for taking the preliminary steps of rupturing the zonule below before applying the forceps are (1) that greater ease is experienced in picking up the capsule that has been relaxed by rupture of a portion of the zonule; (2) that a shorter period of time is required for the delivery of the lens after the forceps have been applied. It is believed likewise that the preliminary pressure is also sufficient to sever the light union, cohesion, or close coaptation that exists at the ligamentum hyaloidea capsulare between the lens and the vitreous without any injury to the latter.

Contraindication to the use of pressure. The initial pressure is not used when there are indications of increased intra-vitreous pressure as evidenced by gaping of the wound, creasing of the incision from puncture to counterpuncture, or repeated prolapse of the iris that resists reposition.

Delivery of cataracts with fragile zonules. The initial pressure applied before any traction is used may accomplish the subluxation of the cataract by the rupture of the inferior zonule. In the experience of the writer it is a fact that it does so in about 15 percent of the cases. Within safe limits it does not do more, else the method of extraction by pressure alone might be more useful. The

writer, in the cases in which subluxation was evident by the rising and movement of the lens, and by the appearance of a dark crescent below the cataract, has not delivered the lens by pressure alone, although this is possible, but has preferred to do so with the aid of traction.

The manipulation of initial pressure is worthwhile. The initial-pressure procedure is worthwhile even in the cases in which subluxation does not occur as a result of this maneuver alone, for it aids in the making of observations that give an index of tissue resistance or lack of tissue resistance; the thickness of the cornea and of the iris; of intraocular pressure; of the resistance of the vitreous; of the support of the lens; of the size of the lens and particularly of the nucleus; of the hardness or softness of the lens; and, in general, of the suitability of the eye to be subjected to the manipulations involved in intracapsular cataract extraction. It is a worthwhile, conservative, useful procedure that does not add to the risk of the operation.

The elevation of the corneal flap and the application of the forceps. Three directly appositional radial sutures are inserted in the corneoscleral tissue after the incision. The writer has described elsewhere⁴ the central suture that is used to retract or elevate the corneal flap in order to obtain a direct view of the iris and of the anterior lens capsule. This maneuver permits the surgeon to observe the efficacy of the size of his incision in relation to the bulk of the lens—if the incision is not large enough it may be increased before the extraction is started. Following Verhoeff's⁵ lead, the upper portion of the capsule has been chosen as the most desirable site for the application of the intracapsular forceps, for it is at this point that they can be ap-

plied to the capsule ever so lightly with the least backward pressure, the capsule being in direct view when the corneal flap is lifted. The grasp at or near the upper equator permits of the manipulations to be described later. It seems preferable, to the writer, not to apply the forceps below: first, because of the curvature of the inferior portion of the lens sloping away from the surgeon's grasp; second, because the capsule and the grasp of the forceps cannot be seen clearly through the hazy collapsed cornea; third, in practice an undesirable backward pressure (be it ever so slight) on the lens must be made in order to pick up the capsule; and, lastly, because certain manipulations are not possible with this lower grasp. If a complete iridectomy has been performed, the forceps may be applied to the anterior face of the equatorial region of the lens capsule in practically the same manner as is done by Verhoeff, and the nucleus tilted by gently pressing on the lower equator with the point of the hook just within the limbus. The grasp of the forceps straddles the new equator of the tilted nucleus. If there is no coloboma, the blades of the forceps held in the left hand are slid beneath the iris, to take hold of the anterior face of the equatorial region of the lens capsule at about 10 or 11 o'clock on the lens dial, or the iris may be retracted and a grasp made at 12 o'clock. When a proper hold of the capsule involving a 4- or 5-mm. area has been secured, as may be known because of the direct view of the area, the traction of the central suture on the corneal flap may be released. The turning of the corneal flap by traction suture does not lead to striped keratitis, loss of vitreous, bullous keratitis, corneal opacity, interference with healing, or other undesirable sequelae. The writer has recently raised the flap after the extraction of the cataract, not routinely but

in many cases, to observe the vitreous and the position of the iris. If the latter is not lying between the edges of the incision the use of the repositor is avoided, thus reducing manipulation and trauma to the iris.

THE WRITER'S METHOD OF MAKING PRESSURE, TRACTION, AND ROTATION

The forceps having been applied to the lens capsule above, they are lifted slightly vertically and drawn toward the surgeon. One may quickly determine whether the inferior zonule has been ruptured by the initial or preliminary pressure or whether the zonule is still intact. If it has been ruptured, the cataract may be delivered quickly and easily with a slight degree of traction and pressure. If the zonule is still intact, then traction toward the surgeon serves to make the inferior zonule in the vertical meridian taut, point pressure being then applied with the expressor at the 6-o'clock position. Rotation is next made clockwise, so that the forceps with the capsule in their grasp are moved to 2 o'clock, while the point pressure is made directly opposite at 8 o'clock, this being the position in which the zonule is made taut by traction at 2 o'clock. Counterclockwise rotation is then made with forceps moved to the 10-o'clock position, and pressure is made at 4 o'clock. By this coördination of rotation and traction, with its effect of tension on the zonule directly opposite, and pressure, the greatest result with the least effort and trauma is accomplished. At the exact moment of making the point pressure the forceps are held still. If a repetition of this point pressure in the three positions once or twice or possibly a third time does not bring about the desired rupture below, it may be said that the limit of safe traction and pressure has been reached. As to time, it is difficult to determine just

how long one may work safely with the zonule to effect intracapsular delivery. It would seem that five minutes should be sufficient to effect the delivery of the average cataractous lens by coördinated traction, rotation, and pressure measures as described, so that it may finally be slid or wheeled out. If a small hole or tear in the capsule above is accidentally made by the forceps, experience has shown that a second effective hold for the delivery of the cataractous lens, in capsule is possible. The rupture of the zonule, the freeing of the lens, and the time for the removal of the cataract by sliding or wheeling it out through the incision are recognized by experienced and alert surgeons. The lens in the ordinary or average case of cataract may be delivered safely in this manner.

There is need for caution. The writer has had a recent experience, which will be referred to later, that caused him to give full value to the manipulations of initial pressure, then to the pressure, traction, and rotation as before described, and to work with the lens in this manner without causing any undue trauma before deciding that the case was not of the ordinary or average resistance or fragility of zonule and before recourse was had to the procedure about to be described.

THE WRITER'S METHOD OF INTRACAPSULAR DELIVERY OF CATARACTS WITH RESISTANT, ELASTIC ZONULAR LAMELLAE

If the ordinary or safe degree of the manipulation heretofore described fails to deliver the lens, it would seem improper to continue the same maneuvers that have proved inefficient for the purpose and that might be dangerous if the pressure and traction were increased. In such cases the capsule is also resistant and does not rupture. It became obvious

to the writer when the difficulties of rupturing resistant, elastic zonules were encountered that other steps should be taken to deliver such cataracts in capsule. In such cases the *stripping of the zonule* from the equator of the lens in the area that is exposed to the direct view of the surgeon has been found to be a feasible and conservative process.

The normal zonule. The normal zonule in a healthy eye is undoubtedly tough, resistant, and elastic. The writer has never had the opportunity to attempt to remove the normal human crystalline lens in capsule. Such experiences should and will be obtained from eyes, otherwise normal, removed because of the presence of malignant tumors at various ages and on fresh (less than one hour deceased) cadavers. It will most probably be found that the zonule is just as tough, resistant, and elastic as were those of the normal monkey eyes on which the writer tested the qualities of the zonule. He has never encountered, even in the most difficult case of cataract in the human eye, anything approaching the resistance of this normal monkey zonule. There is undoubtedly always some degeneration of the zonule accompanying the development of cataract.

The zonular lamella. The term zonular "lamella" is used because, during the writer's intracapsular operations, attachment of the zonule has been observed to be in the form of a membrane or lamella. When a coloboma has been made by complete iridectomy and the lens is lifted vertically and tilted by the combined action of the forceps and hook, the equator may be plainly seen; extending from this, in cases favorable for such observations, is a thin semitransparent, crinkly, glassy, or cellophanelike sheet of zonular lamella. Troncoso,⁷ Duke-Elder.⁸ Gold-

smith,⁹ and others have described the parts of this zonular membrane. Apparently the strongest or most important part is attached to the anterior equatorial area of the lens. Through the zonular membrane, when the lens is lifted, may occasionally be seen the face of the vitreous, and one is enabled to determine whether the vitreous body is relaxed and in a correct posterior position, or whether it is under tension and bulging forward. There is normally more or less space between the equator of the lens and the zonular lamella and the face of the vitreous. In normal cases this space is at least 3 mm. deep when the lens is lifted, and only in such cases may the maneuver of stripping the zonule from the equator of the lens be employed.

The instrument used in the stripping of the zonule. With the lens-capsule forceps holding the superior equator of the lens slightly upward in a safe position, the elbow of the lens-expressor hook is applied to the curved surface of the easily visible equator of the lens, and the zonular lamella, which is under tension by being lifted, is thus stripped from the equator. The attachment of the zonule, which previously seemed tough and resistant, now seems to dissolve at the most gentle touch. First a dehiscence is seen, then a disinsertion, and finally a circumferential tearing on rotation occurs. Here again the principle of tension through traction and the application of point pressure for the greatest effect with the least effort is employed. After tearing of the central area of the zonule has started, the lens is rotated clockwise to 2 o'clock on the corneal dial, and the zonule touched or stripped from 12 to 10 o'clock, then counterclockwise rotation is made to 10 o'clock and the zonule touched or stripped from 12 to 2 o'clock. At the exact time of the touching or stripping,

the forceps, having effected the tension by traction and rotation, are held still. A variation that may occur is that of circumferential tearing, which may develop on rotation when once a dehiscence or disinsertion has been started.

The final delivery of the cataract after stripping of the zonule. Between 10 o'clock and 2 o'clock the zonule is exposed over an arc of 120 degrees, and is vulnerable, in direct view, to a safe approach of direct interference by the surgeon by means of coördinated traction, rotation, and pressure. When once disinsertion has been effected over these 120 degrees, further tearing generally occurs fairly easily by rotation combined with pressure, inferiorly, through the cornea, opposite the point of traction. One may finally deliver cataractous lenses with resistant zonular lamellas safely, sliding or wheeling them out without continued or excessive pressure and without repeating efforts that are ineffective.

The discovery of the maneuver of stripping of the zonule. The maneuver of stripping the zonule was first discovered by the writer when he saw it occur as he was lifting the border of the iris over the equator of the lens with the aid of the elbow of the lens-expressor hook. This observation, and the further tearing of the zonule on rotation of the lens, led him to attempt this stripping of the zonule in other difficult cases.

The removal of the embryo lens in capsule. The author's experience in removing the crystalline lens of the 5-day chick embryo is interesting in connection with the latest procedure of stripping the zonule from the equator of the lens when cataract has formed. The reader may be familiar with the research¹⁰ of the writer on the cultivation of crystalline-lens epi-

thelium *in vitro* and the manner of obtaining the specimen of lens epithelium not contaminated by other cells. The writer removed the vitreous, lens, and a ring of pigment from the eye of the 5-day-old chick embryo and by microscopic ($\times 24$) dissection removed the lens from the other tissues by stripping the zonule from the equator of the developing lens. It was perfectly feasible at this stage of development. At the later stages of embryonic development the zonule became more resistant, and it was more difficult to remove the lens in capsule.

The recent experience which taught the writer caution. The recent experience that caused the writer to revalue the manipulations which he has used and described for the intracapsular extraction of cataract in eyes with intact zonule was that of the loss of a small amount of vitreous in a manner that seemed directly connected with the stripping of the zonule above. It was the first experience of its kind in a consecutive series of approximately 300 patients operated upon in a period of six years since the maneuver of the stripping of the zonular lamella from the equator of the lens was first used. In the early part of this period final recourse was had to this manipulation only in about 15 percent of the cases. No reference was made to it even though it was shown in motion pictures of the writer's surgery in many places. After the publication of the article¹ dealing with this as a new method, the desire expressed by visiting surgeons to see the method led to its gradually being used more and more even to a slight degree in cases in which delivery might have been effected if the coördinated pressure, traction and rotation had been persisted in for a slightly longer period of time.

In the case referred to the eye was operated upon very recently—in May,

1943. The indications seemed clear for an uncomplicated intracapsular delivery with round pupil. The pupil was well dilated. After a short period of initial pressure, then pressure, traction, and rotation, the inefficiency of the grasp of the forceps on the capsule midway between the upper equator and the central area of the lens became apparent.

The lens in which an immature cataract had developed, was soft; it had a small nucleus which did not tilt well on pressure. The grasp of the capsule away from the equator did not permit the upper pole to be lifted well. The zonule did not rupture easily. Stripping of the zonule above was resorted to at an early stage and under the disadvantage of not having the superior equator properly lifted away from the vitreous body. Separation of the zonule from the equator was effected through an arc of 90 degrees but vitreous presented and finally a small amount was lost upon delivery of the lens in capsule. It can be truthfully reported that this is the first such case in which the vitreous was endangered or lost as a result of this special manipulation. The lessons to be learned are four in number: (1) The decision that the case is a difficult one and that the zonule is too resistant to be delivered safely by pressure, traction, and rotation otherwise should not be made until these maneuvers have been given their full value. (2) The method of stripping the zonule should not be regarded as one which may be applied to all classes of cataract. It should be reserved for the cases which are proved difficult by the failure of preceding manipulations and by observations and should be part of a system of intracapsular cataract extraction. (3) Surgeons who use the method should not plan to do it in a particular case before the operation is in progress. (4) Particular care must be exercised in the place-

ment of the grasp of the forceps. The area of the capsule picked up should be very close to the anatomic equator of the lens. In practice when there is a hard nucleus of the lens which will tilt on pressure, the capsule over the new or adventitious equator of the tilted lens may be straddled and grasped. If the lens is soft, the capsule at the anterior face of the equator may be grasped. This is more easily accomplished in the presence of a complete coloboma by iridectomy. With the round pupil, especial care must be exercised to place the forceps on the peripheral part of the capsule. The observation that the zonule is lifted free from the hyaloid of the vitreous must be made before the stripping of the zonule is begun.

Preparation for cataract extraction in a difficult case. If a difficult extraction is anticipated in a certain case, as in a relatively young person, 30 to 50 years of age, who has a resistant zonule, a complete iridectomy may be done, the advantage of the round pupil being given up for the greater ease of operating and the safety of the delivery of the cataract in capsule. If the round-pupil operation has been started and capsule has been grasped in an advantageous position near the upper equator, the grasp should not be relinquished. In such difficult cases the zonule can be safely stripped off, but if the grasp is poorly placed it may be well to give it up, even though a second grasp in the same or different area will expose the weakness of the area of the capsule first grasped and may lead to its rupture at that site. If the important feat of a grasp near the equator is not accomplished and the lens cannot be lifted satisfactorily from the vitreous body, the stripping operation should not be employed. If the iris has interfered too much, a complete coloboma should be

made for the second attempt. There are cases in which it seems desirable to shift the placement of the forceps on the capsule at or near the lower equator and to effect the delivery of the lens by tumbling. However, there is no possibility of using effectively any other maneuvers than those of traction and pressure and limited rotation with the forceps in the lower position. The writer is convinced of the advantages of the grasp at or near the upper equator.

Results. A report of statistics of results obtained following the procedures described in the system of intracapsular cataract surgery is in the press and will appear shortly.

SUMMARY AND CONCLUSIONS

The development of a system of intracapsular cataract surgery by which particular techniques are adapted to the case in hand has been described. The basis of the system is concerned chiefly with the condition of the lens capsule, cortex, zonule, and vitreous. Observations made before and during the progress of the operation guide the surgeon in his selection of the procedure to be employed. An ineffective procedure is not repeated. The application of the system has been made not only to the eyes with cataracts in which the zonule is intact but also to those in which the lens is luxated or subluxated. The description of procedures applicable to the latter more or less follows the literature, except for the suggestion that at times it may be necessary to strip off the resilient, resistant portion of zonule that is present in the case of young persons who have congenital malformations.

The methods used in intracapsular extraction in cases with intact zonules represent a further development of the procedures that have been previously de-

scribed by the writer. The cases are divided into three classes: First, a small group of those in which the zonule is fragile, and traction or pressure alone or a combination of them may be employed for the relatively easy delivery of the cataract. Second, the large group of cases in which the zonule has the average resiliency and resistance and in which an average degree of pressure, traction, and rotation of the lens clockwise and counterclockwise should succeed. The exact method of using these procedures is described. Third, a small percentage of cases in which the zonule exhibits greater-than-the-average degree of resistance and in which, when this is recognized, the maneuver of stripping off the zonule is resorted to after the other procedures have been used within the limits of safety. A particular case is described

which taught the need for caution. It is recognized that in all cases of cataract formation there is more or less degeneration of the zonule. It is worthwhile to have a procedure which is effective and safe, when used properly, when others have failed. The conditions under which the manipulations of stripping off the zonule may be employed are described in detail. A report of statistics or results obtained following the procedures described in the system of intracapsular surgery is in the press and will appear shortly. The author's procedures for intracapsular surgery have been described before, but not in the present systematic form. It was said before that they were feasible. Now it is reported that they are conservative and desirable.

A COMPARISON OF THE OCULAR REACTIONS OF PIGMENTED AND ALBINO RABBITS TO NORMAL HORSE SERUM*

INTRAOCULAR FOLLOWED BY INTRAVENOUS INJECTION

T. F. SCHLAEGEL, JR., LT. (MC), M.D.
Indianapolis

The purpose of this report is fourfold:

1. To compare ocular reactions in pigmented and albino rabbits.
2. To use an allergic mechanism consisting of intraocular followed by intravenous injection of normal horse serum.
3. To compare effects observed at three different intervals of time intervening between intraocular and intravenous injections: 1, 7, and 14 days.
4. To study the histopathologic features of the injected and fellow eyes at variable periods after the intravenous injection.

Schlaegel and Davis¹ have shown that a close resemblance to the histopathologic picture of sympathetic ophthalmitis can be produced in rabbit eyes receiving an injection of normal horse serum. This report is a continuation of a study of the reaction of the rabbit eye to normal horse serum, using another allergic mechanism and employing a comparison of the reaction in pigmented and albino rabbit eyes.

Seegal and Seegal² showed that "Eyes which had been sensitized with a foreign protein uniformly failed to respond to the intravenous injection of the homologous substance until at least the fifth day. Although slight inflammatory response could be produced in a few animals on the sixth to the tenth day after sensitization, it was quite evident from the majority of experiments that the eye response reached a maximum from the tenth to the fifteenth day or even later after local sensitization."

* From the Research Division, Indiana University School of Medicine, Indianapolis, Indiana.

The report of Seegal and Seegal considered only the gross ocular reactions. This report includes both gross and microscopic studies.

The comparison of pigmented and albino rabbits was undertaken in an attempt to throw some additional light on the pigment-allergy theory of sympathetic ophthalmia. A minor purpose was to compare results with those of Riehm³ who concluded that horse serum absorbed from one eye produced an elective sensitivity in the fellow eye, resulting in uveitis in pigmented rabbits but not in albinos. This conclusion was based on experiments with 18 rabbits, 2 of which were albinos. His method was to drain the anterior chamber of the right eye and to replace the aqueous with the same amount of horse serum. The point of the needle was inserted into the root of the iris and 0.25 c.c. to 0.50 c.c. of horse serum was injected. He used various procedures in each of the 18 animals. As an example of the type of procedure and of the results obtained, there follows a report on one of his pigmented and on one of his albino rabbits.

His pigmented rabbit number 144 was injected, as herein described, on the 1st, 12th, 13th, and 14th days, with a total of 1.05 c.c. of horse serum. An intravenous injection of 20 c.c. of horse serum was given on the 40th day; an iritis developed and reached its height on the 47th day. The periphery of the choroid was invaded by foci which gradually became pigmented and resembled fine spotted chorioretinitis. On the 139th day he gave a second intravenous injection of 20 c.c. which was followed in 7 days by a recur-

rent iritis and cloudy cornea. On the 155th day, under atropine mydriasis, he observed at least 100 rather large and new white foci of the choroid.

His albino rabbit number 147 was injected in the right eye on the 1st, 11th, 13th, 15th, 17th, 22d, 46th, and 57th days.

applications of 2 drops of 4-percent butyn. A 27-gauge needle was inserted 5 mm. behind the limbus at the 12-o'clock meridian. One tenth of a cubic centimeter of normal horse serum was then injected into the vitreous.

Three series of rabbits were used. In

TABLE 1

GROSS LIVING AND MICROSCOPIC RESULTS OF THE INJECTION OF NORMAL HORSE SERUM THROUGH THE CILIARY REGION OF THE RIGHT EYE FOLLOWED BY AN INTRAVENOUS INJECTION *one day* LATER

* + =slight reaction as sluggish pupillary response and slight congestion at the injection site.

++ =moderate congestion and slight iritis.

+++ =pronounced congestion, chemosis, and more iritis.

++++ =extreme congestion, chemosis, strands of exudate on iris and in pupil.

0 =no change in eye.

** 1+ =minimal cellular infiltration of uvea or upon optic disc—always by monocytes, often by lymphocytes and epithelioid-like cells also.

2+ =cellular infiltration by monocytes, lymphocytes, and epithelioid-like cells filling the normal thickness of the choroid.

3+ =distension of choroid by cellular infiltration sometimes including giant cells.

4+ =distension of choroid to several times its normal thickness always including giant cells and many epithelioid-like cells.

† 1+ =one or two giant cells in routine six sections.

2+ =three to 10 giant cells in routine six sections.

3+ =over 10 giant cells in routine six sections.

The total injection of horse serum was 2.5 c.c. During this treatment he failed to find any changes in the left eye. After 20 c.c. of intravenous horse serum was injected on the 111th day, he noticed only conjunctival injection and spastic pupil in the left eye.

PROCEDURE

For this report the following procedure was followed: All rabbits were examined grossly at the start with the aid of a flashlight, and those with eyes inflamed from any cause were discarded. The right eyes were anesthetized by three

the first series (table 1) 5 pigmented rabbits received an intraocular injection, followed 24 hours later by an intravenous injection of 1.0 c.c. of normal horse serum. The eyes were then enucleated at variable periods from one-half to 14 days. This series was considered a test group, since from the work of Seegal and Seegal we did not expect to obtain a reaction.

The second series (table 2) was composed of 12 pigmented and 12 albino rabbits. (Some of the rabbits died and were replaced by rabbits treated in the same manner.) The intravenous injection

followed the intraocular injection by seven days. At each of 6 different intervals from one-half to 21 days, 2 pigmented and 2 albino rabbits were killed and their eyes enucleated.

The third series (table 3) also was

right and left) of series 2 and 3 which were apparently normal in the routine 6 sections were studied further in 6 more sections cut in different areas. To ascertain correctly the absolute amount of infiltration, serial sections should be made,

composed of 12 pigmented and 12 albino rabbits. (In this group also some of the rabbits died and were replaced.) The procedure differed from that of series 2 only in that the interval between intraocular and intravenous injection was 14 days.

In all three series the gross reactions were studied the days following the intraocular and intravenous injections. Routinely, six sections stained with hematoxylin and eosin were made of both right and left eyes. But all eyes (both

but it was felt that in this experiment such a procedure would not be worth the effort required.

GROSS REACTIONS

After the intraocular injection, the right eyes as a rule showed only a minimal reaction such as would be expected to result from the trauma of injection. However, a few of the right eyes responded to a degree greater than the expected minimum. This may have been

due to the activation of a latent ocular infection or to a transient infection incident to the injection.

After the intravenous injection in series 1, there was no increase in the minimal response. In series 2, one third of the animals, and, in series 3, more than one half of the animals developed a more

substance until the fifth day and the reaction is maximum at about 14 days.

Further evidence that 14 days is a period of maximum allergic response is seen in the high percentage of rabbits which died in convulsions a few minutes after the injection. One fourth of the animals in series 3 died in this manner as

than minimal reaction. This increased reaction was found more frequently in the right eyes of albino rabbits than in the right eyes of pigmented rabbits. The reason for this may have been the greater visibility of congestion in albino irides.

Thus we confirm, in our limited series, the conclusions of Seegal and Seegal that rabbits fail to respond *grossly* to the intravenous injection of the homologous

compared to one eighth of those in series 2 and none in series 1.

In all three series the left eyes consistently failed to show gross evidence of reaction.

MICROSCOPIC RESULTS

In this report attention is focused on the histopathologic features.

Series 1 (table 1). The number of

rabbits is inadequate. The right eyes were free of cellular infiltration until seven days after the intravenous injection. The response at 7 days was moderate and the one at 14 days pronounced.

A detailed report of the histopathologic findings will not be given, as they were very similar to those previously

one pigmented (half of those enucleated after 12 hours) were found to have cellular infiltration of the uvea. The degree of cellular infiltration was more pronounced in the pigmented group.

All *left* eyes were apparently normal in the routine six sections, but further study in six more sections revealed a

Fig. 1 (Schlaegel). The ciliary body is swollen by a mononuclear infiltration to over twice its normal size. A nodule of epithelioid-like cells (including a small giant cell) is bursting through the pigment epithelium into the vitreous. Part of a dilated and engorged vein is on the left.

reported.¹ P758 was a typical four-plus reactor (fig. 1). There was a dense uveal infiltration which swelled the choroid to several times its normal thickness. The cells were mainly monocytes with a fair percentage of lymphocytes, plasma cells and epithelioid-like cells, and a few giant cells. There was slight perivascular infiltration of the sclera. The retina was disorganized and had gliosis on its surface. The pigment epithelium was scalloped owing to ballooning of its cells, and the iris was densely infiltrated in its posterior half.

Series 2 (table 2). In this series all right eyes but that of one albino and of

slight uveal infiltration in 5 of the 12 pigmented and in 5 of the 12 albinos.

Guillery⁴ in his work using tuberculoxins as a sympathogenic agent has said that by studying all sections he has yet to find an experimental animal with no findings in the secondary eye. It has also been the experience of pathologists that serial sections will often make possible a diagnosis of sympathetic ophthalmia in enucleated human eyes when a few routine sections fail to show the characteristic change.

It must be kept in mind, however, that the infiltration in the left eyes was very slight. Also, in a study of a series of un-

treated apparently normal rabbit eyes, such an infiltration was occasionally found. We cannot conclude, therefore, that all of the slight infiltrations in either right or left eyes were due to a reaction to horse serum.

Series 3 (table 3). In this series the microscopic cellular infiltration as well as the gross clinical reaction reached its

tigen-antibody complex after 14 days.² The stimulating agent is probably the lipoids or their derivative fatty acids.^{6, 1}

It is interesting that in series 3 both the gross and microscopic reactions were no more severe than if no intravenous injection had been made.¹ Apparently the intravenous injection was a superfluous addition to the allergic reaction that occurs

Fig. 2 (Schlaegel). The folds between the densely infiltrated ciliary processes are filled with an exudate consisting mainly of epithelioid-like cells.

height. The severity of the infiltration in the pigmented and albino subgroups was equal.

It has already been shown that rabbits receiving only an intraocular injection of normal horse serum fail to respond until after about 14 days.¹ This "incubation period" may depend on the time necessary for the vitreous lipase⁵ to cause sufficient change in the horse serum to release the active exciting agent. Or it may depend on an allergic reaction as a result of the development of an an-

after 14 days in eyes receiving only an intraocular injection. However, in both series 1 and 2 definite cellular infiltration appeared before 14 days had elapsed. It is thus probable that in the first two series the activation of the horse serum in the right eyes was hastened by the allergic response to intravenous horse serum. Although an allergic reaction was not observed grossly in series 1, there may have been an intraocular change undetected by external examination.

Of the left eyes, 4 of the 12 pigmented

and 5 of the 12 albino rabbits had a slight uveal infiltration. Although the infiltration was minimal, it was of the same character as an infiltration of similar degree in the right eyes. It consisted of one or two small nodules of monocytes and lymphocytes in the uvea and had none of the features of tubercular granulation tissue seen in the right eyes of severe reactors.

DISCUSSION OF HISTOPATHOLOGY

Polymorphonuclear leucocytes were uniformly absent from all the sections studied. This was probably due to a change of the normal alkaline condition of the eye to the acid side of neutrality as a result of the first intraocular injection.¹ Polymorphonuclears predominate when the tissues are alkaline but are replaced by mononuclear cells when the tissues become acid.⁷

There are two histopathologic features of the reaction of the rabbit eye to normal horse serum which we failed to discuss in our previous paper:

1. E. Fuchs⁸ pointed out that in sympathetic ophthalmia a cellular infiltration consisting mainly of epithelioid cells is seen to break into the vitreous from the ciliary body, filling the spaces between the folds of the corona ciliaris. Such a response was observed in our intense reactors (fig. 2). The filling-in of the folds is another fact further² differentiating the reaction to normal horse serum from that of panophthalmitis, for in panophthalmitis the cells lodge at the tips of the corona.

2. E. Fuchs⁸ also described a bursting of epithelioid cells

from the choroid into the subretinal tissues and even into the vitreous. The boundaries of the cells become sharper and assume a spindle shape. They may grow to form long thin strands. These cells are distinguished from true connective tissue because they stain yellow with Van Gieson stain, whereas connective tissue stains red. Such a phenomenon was observed in a few of the severe reactors (fig. 3).

Sabin, Doan, and Forkner⁶ have pointed out that the epithelioid cell is not

Fig. 3 (Schlaegel). Elongated spindle-shaped cells are growing out from the choroid into the vitreous.

the immediate reactor to active chemical substances. Preceding its appearance there is a maturation of new young monocytes. They found the epithelioid cells appearing by the fourth day.

In this experiment epithelioid-like cells were seen by the fourteenth day in series 1, after the first day in series 2, and after

by supravital staining) are more typical in appearance. It may be that the cells previously described, and many seen in the sections of this experiment, were young and in the stage of transformation from monocytes to epithelioid cells.

Although epithelioid-like cells were usually present, they were not always

Fig. 4 (Schlaegel). (Albino 187.) Two giant cells (one foreign-body type and one Langhans type) are seen lying in the choroid surrounded by a diffuse infiltration consisting mainly of epithelioid-like cells. The giant cells have engulfed cellular debris.

one-half day in series 3. These time intervals are measured from the time of intravenous injection. The total period from the time of the first injection into the right eye was more than four days in all three series. The epithelioid-like cells were found in greatest number early in the third series.

In a previous paper¹ we defined the term epithelioid-like cell and used it for cells appearing like epithelioid cells except that the nucleus was usually round instead of the characteristic bent shape. In this series the epithelioid-like cells (a term we shall continue to use because we do not have proof that they are epithelioid cells

found and were seldom present in great numbers except in eyes with a three- or four-plus reaction. E. Fuchs⁸ pointed out that epithelioid cells are often difficult to find and may possibly be lacking entirely in sympathetic ophthalmia. He also noticed that they were more numerous when the cellular infiltration was intense.

A comparison of the giant cells in the pigmented and albino groups failed to reveal any essential difference. Both foreign-body and Langhans types were present. In the pigmented group these cells had phagocytosed pigment granules, whereas in the albino group other debris was present in the cytoplasm (fig. 4). In

regard to the scarcity of giant cells in the infiltration in this experiment, it should be pointed out that Fuchs stated they were present in but one half of his cases of sympathetic disease.

COMMENT

Upon comparing the results of this ex-

periment with those of a method previously reported,¹ in which the rabbits were first sensitized by intradermal injections and then injections were made into the right eye, we find that the degree of cellular infiltration is less and the number of giant cells is fewer.

right eye. Also, the gross reaction in the first four albino rabbits was very minimal. Our premature impression, therefore, was that albino rabbits were not going to respond to the intraocular followed by an intravenous injection of normal horse serum. However, upon doubling the number of rabbits and upon a search in

Fig. 5 (Schlaegel). Two nodules of epithelioid-like cells are lying in a heavy mononuclear infiltration of the choroid.

periment with those of a method previously reported,¹ in which the rabbits were first sensitized by intradermal injections and then injections were made into the right eye, we find that the degree of cellular infiltration is less and the number of giant cells is fewer.

The conclusion of Riehm,³ that horse serum absorbed from one eye produces an elective sensitivity in the fellow eye resulting in uveitis only in pigmented rabbits, has been much quoted. This conclusion was based on gross and ophthalmoscopic findings and apparently did not include microscopic study. In series 2 of this experiment, the first four albino right eyes studied were found to be normal, as compared to only one normal pigmented

additional sections we found this presumption to be untrue.

Although the cellular infiltration in the left eyes was minimal, there was an equal response in pigmented and albino rabbits. If we had used horse serum in as large doses and with as repeated injections as did Riehm, it is possible that the response in the left eyes would have been more intense. Although no essential difference was found in the reaction in pigmented and albino rabbit eyes, it must not be concluded that the pigment-allergy theory is discredited. The procedure here followed is, most probably, far removed from the actual etiologic mechanism of sympathetic ophthalmitis. Also the involvement of the left, or sympathizing eyes, was far too

slight to be conclusive. The pigment-allergy theory has much factual backing, and pigment very likely plays some role in the development of sympathetic ophthalmia.

However, tubercular granulation tissue such as is seen in sympathetic ophthalmia has been shown to be due to the stimulation of some lipoids or their derivative fatty acids.⁶ Therefore, it is improbable that melanin is the actual exciting agent since as far as we know it does not contain lipoids or fatty acids.⁹

CONCLUSIONS

1. Gross and microscopic ocular reactions were essentially equal in pigmented and albino rabbits.

2. The allergic mechanism of intraocular followed by intravenous injection of normal horse serum is less effective in producing gross and microscopic results than the method of sensitization by intradermal injection prior to injection made into the right eye.

3. Gross and microscopic reactions were most pronounced when the intravenous followed the intraocular injection by 14 days.

4. The microscopic picture of the injected eyes of severe reactors bore a close resemblance to that of sympathetic ophthalmia. The uveal infiltration in the non-injected eyes was very slight but was present in 40 percent of the cases.

PRESENT LIMITS OF GONIOSCOPY*

PETER C. KRONFELD, M.D., AND H. ISABELLE MCGARRY, M.D.
Chicago, Illinois

After having been a scientific hobby of a few investigators for about 30 years, gonioscopy has finally become a routine method of examination in many clinics and private offices. A wealth of new observations has been made and recorded in the literature.¹ To take inventory of the new knowledge, as far as it pertains to the glaucomas, could be done in several ways. We have chosen to do it by stressing the present limits of gonioscopy, limits as they apply to the physical procedure, to the availability of definite, characteristic findings and to the interpretation of such findings. Such a presentation may serve to define the present-day status of gonioscopic knowledge more briefly and concisely than would a discussion of all the established facts.

Gonioscopy has been expected to give information with regard to: (1) the patency or accessibility of the angle of the anterior chamber; (2) the function or permeability of the corneoscleral trabeculum; (3) involvement of the anterior portion of the ciliary body in an inflammatory or neoplastic disease of the uvea; (4) abnormal tissue-elements or foreign bodies in the angle; (5) how and why surgical operations in the region of the angle have succeeded or failed to normalize the intraocular pressure.

In the glaucomas gonioscopy is chiefly concerned with items 1, 2, and 5. The part played by peripheral anterior synchiae (PAS) in the mechanism of the glaucomas has certainly been greatly elucidated and clarified by the advent of gonioscopy, but it would not be true to

say that gonioscopy has "straightened us around" on that subject. Even in the pregonioscopic era we knew from pathologic as well as clinical observations that among the so-called primary glaucomas there are: (1) cases in which closure of the entrance to the chamber angle by contact between iris and lateral angle wall constitutes the primary pressure-elevating mechanism, and (2) cases in which the intraocular pressure becomes and remains elevated in the presence of an entirely open angle. It was also known that in some of the cases of the latter group during the course of the glaucoma PAS can develop which have not played a part in the original pressure-elevating mechanism but may aggravate the situation. While it is true that the names, "congestive" or "inflammatory" on the one hand and "chronic simple glaucoma" on the other hand did not express the principal difference between the two types of glaucoma, the existence of such a difference was fully realized in the pregonioscopic era. Our enthusiasm over the classification of the so-called primary glaucomas into the narrow-angle and the wide-angle type (O. Barkan), which terms express the principal difference between the two types much more clearly, should not make us forget that their existence had been postulated from anatomic as well as clinical evidence long before anybody ever saw the chamber angle in a living eye.

With regard to the narrow-angle type, it may be of interest to hear that W. Czermak² in 1897 gave a fairly accurate description of its mechanism: "Through progressive senile increase in the volume of the lens and perhaps also of the ciliary processes . . . the anterior chamber of the senile eye becomes shallow, which consti-

* From the Illinois Eye and Ear Infirmary (Chief of Staff, Dr. Harry S. Gradle). Read before the Chicago Ophthalmological Society, March 15, 1943.

tutes a predisposition to glaucoma. If the pupil dilates under the influence of a mydriatic or in the dark as through stimulation of the sympathetic, the crowded-together root of the iris comes in contact with the posterior surface of the cornea and the connection between anterior chamber and chamber angle is closed off. By continued action of Schlemm's venous plexus the aqueous is siphoned out of this closed-off pocket. The pressure in it drops while it rises in the remainder of the anterior chamber. Thus the root of the iris . . . is sucked or, by the pressure of the aqueous in the posterior chamber, pressed into the angle."

The concept of a temporary contact between iris and lateral angle wall as a cause of acute rises of the intraocular pressure in anatomically predisposed eyes received support from the clinical studies of Gröenholm,³ Seidel and Serr,⁴ and, finally, was proved to be correct by H. S. Sugar's gonioscopic observations⁵ of the actual occurrence of the contact immediately before the rise of intraocular pressure. Gonioscopy thus has played an important part in establishing the mechanism of narrow-angle glaucoma. Practically, it has enabled us to determine whether or not in a given case the anatomic predisposition—namely the narrowness of the entrance to the angle—is present. This is an important point, since narrowness of the angle entrance is not always associated with all-over shallowness of the anterior chamber.

The gonioscopist sometimes finds it difficult to answer the question, whether or not an eye with a certain degree of narrowness of the angle is actually in danger; that is, whether the angle-crowding that is likely to occur in normal life is sufficient to lead to temporary closure of the entrance to the angle. He tries to answer this question by investigating (after Sugar) the effects (1) of moderate mydriasis produced by drugs, and (2) of

accommodation. If both of these two angle-crowding factors do not bring the iris in contact with, or very close to, the lateral angle wall, the gonioscopist is tempted to consider the degree of angle narrowness as innocuous and the patient not in danger. The question is whether we actually know and are able to reproduce at will all natural angle-crowding factors. Besides emotion (through factors other than mydriasis) and upper respiratory infections which were considered by Sugar in his work on the mechanism of acute glaucoma,⁵ there may be still other angle-crowding factors. While the general opinion seems to be that eyes with potential or definitely established narrow-angle glaucoma differ only in one respect from the normal eye—namely, in their anatomic angle configuration—there is a remote possibility that the anterior uvea in these eyes does undergo sudden increases in volume to a greater extent than does the normal eye. In a number of cases in which artificial mydriasis plus accommodation did not produce closure of the entrance to the angle and therefore no embarrassment of the intraocular pressure, weeks or months later a spontaneous rise of the intraocular pressure occurred which could not be attributed to any *known* angle-crowding factor. The practical conclusion should be that the distinction between dangerously or innocuously narrow angle entrances cannot always be made with absolute certainty and that any eye with marked narrowness should be considered as being in danger.

To what extent the angle, in established narrow-angle glaucoma, has become closed off by permanent peripheral anterior synechiae (which develop if the contact is not interrupted fairly promptly by miotics, surgery, or spontaneously) can usually be determined with great accuracy. Difficulties arise in the extreme degrees of shallowness of the anterior chamber in which one usually finds rela-

tively small and flat corneas combined with an extreme forward-position of the iris-lens diaphragm. In gonioscopic lingo, in these cases, we are not able to get over the iris hump. It seems unlikely that by a further modification of the contact lens some of these angles could be rendered visible. As stated by Sugar, the lens of type A seems more suitable for the examination of such shallow chambers than the lens of type C. Still, certain angles have to be described as being too shallow for gonioscopy and the question whether there is a narrow cleft leading down to the apex of the angle or whether there are peripheral anterior synechiae has to be left unanswered. We have found that when the PAS reach considerable extent in meridional direction the iris hump does become less pronounced, the iris taking on the shape of a chord where it used to be an arc. Thus the presence of flatter, straighter iris sectors in eyes with very shallow anterior chambers is suggestive of PAS in those sectors.

The presence of corneal edema is no insuperable obstacle since by massage with a glass rod, according to Larsson,⁶ or by the instillation of glycerine (Cogan⁷), a portion of the cornea can be cleared sufficiently to permit gonioscopy.

The close parallelism between closure of the angle and elevation of the intraocular pressure which has been found in innumerable instances in which before the formation of the PAS the intraocular pressure was normal, constitutes weighty evidence in favor of the concept that the human eye depends largely upon the trabeculum-canal-of-Schlemm mechanism for maintenance of a normal intraocular pressure. Because of the general importance of this concept the closeness of this parallelism between closure of the angle and intraocular pressure in eyes without any artificial new outlet for the intraocular fluid has been the subject of special investigation. An apparent lack of paral-

lelism is seen occasionally in eyes with acute congestive glaucoma in which an iridectomy completely and permanently controls the intraocular pressure although most of the chamber angle seems to be closed. A similar situation is found in a very small percentage of the cases which, as a result of prolonged absence of the anterior chamber after cataract operations, have developed extensive PAS. Such exceptions from the general rule of parallelism have been explained by Sugar⁸ as being due to minute iris incarcerations which, while not big enough to cause any visible permanent gaps in the operative incision associated with gross blebs in the overlying conjunctiva, allow a sufficient amount of filtration to keep the intraocular pressure at a normal level. In some of these cases Sugar was able to "raise" minute blebs by massage of the eye. The presence and patency of such minute subconjunctival fistulas is difficult to prove conclusively. There have been a number of histologic reports indicating their presence where they had not been seen nor expected clinically. On the other hand, small iris incarcerations in the presence of closed angles very often fail to control the intraocular pressure permanently, especially if in the eye in question the natural channels of outflow were insufficient before the PAS formed. Whatever the role of small iris incarcerations may be, there are cases of narrow-angle glaucoma which have been controlled by iridectomy without iris incarceration although more than three quarters of the angle appeared to be closed. To us these cases seem to indicate that in narrow-angle glaucoma in which the normal channels of outflow function normally until the entrance to the angle becomes obstructed or PAS form, a small accessible portion of the trabeculum is sufficient for maintenance of normal intraocular pressure. It also seems possible that in such eyes filtration takes place through tiny

gaps in the PAS as well as around the synechiae into open-angle pockets.

All in all, gonioscopy gives satisfactory explanations for most of the phenomena observed in narrow-angle glaucoma. The name seems to have been well chosen, the closure-inviting narrowness of the angle being the main if not the sole cause of the glaucoma. The term "wide-angle glaucoma" has no such positive meaning; it refers to a negative characteristic of this large and very heterogeneous group of glaucomas; namely, the absence of any visible obstacle to the passage of aqueous into the trabeculum. What little there is in the way of positive characteristics of this group, could not be included in its name. Here the limits of gonioscopic knowledge are very apparent. In the absence of any obstruction within the angle the gonioscopist's natural move was to look for signs of decreased permeability of the corneoscleral trabeculum. O. Barikan even went so far as to use the term "trabecular" as a synonym for wide-angle glaucoma and as the counterpart to narrow-angle or iris-block glaucoma, although he does mention, under the general heading of trabecular glaucoma, a secretory or neurogenic variety.

The gonioscopic recognition of impaired function of the corneoscleral trabeculum has proved most difficult. In our work on the visualization of the canal of Schlemm by drawing blood into it,⁹ we observed a few cases of advanced wide-angle glaucoma in which the trabeculum seemed definitely less transparent than normally, which may have been a sign of sclerosis. Bangerter and Goldmann¹ describe veiling of the anterior surface of the ciliary body in some of their wide-angle glaucomas, which may have meant lessened permeability of the uveal portion of the trabeculum that overlies the ciliary body. This veiling, unless it is very pronounced, may be difficult to recognize and to distinguish from the normal. We

have seen it, but it is rare.

Gonioscopy has been responsible for a revival of or renewed interest in the pigment-block theory of some glaucomas. A considerable percentage of all wide-angle glaucomas show excessive pigmentation of the trabeculum, but in the majority of them the degree of trabecular pigmentation varies within the same wide limits as in nonglaucomatous eyes of the

TABLE 1
RELATIVE INCIDENCE (PERCENTAGE) OF THE VARIOUS DEGREES OF TRABECULAR PIGMENTATION IN NONGLAUCOMATOUS AND WIDE-ANGLE GLAUCOMATOUS EYES OF SUBJECTS OVER 40 YEARS OLD

Degree of Pigmentation	Controls		Primary Wide-Angle Glaucoma	
	Iris blue or gray	Iris hazel or brown	Iris blue or gray	Iris hazel or brown

Moderate	11	32	40	32
Excessive	0	0	20	23

same age and racial group. Table 1 shows the degree of pigment infiltration of the trabeculum in 200 nonglaucomatous and 150 wide-angle glaucomatous eyes of individuals over 40 years of age.* While these numbers are probably too small and the estimation of the pigment content by gonioscopy too inaccurate to permit definite conclusions, the amount of pigment present in the trabeculum of nonglaucomatous eyes seems to depend upon the pigment content of the iris, and excessive pigmentation seems to occur only in glaucomatous eyes. Thus only excessive pigmentation has come to be recognized as being characteristic of some wide-angle glaucomas in which it has diagnostic significance. It must be remembered that the absence of excessive pigmentation by no means rules out wide-angle glaucoma. In many wide-angle glaucomas the appear-

* This work was done by Drs. H. S. Koch and T. H. Luo in the Glaucoma Clinic of the Illinois Eye and Ear Infirmary.

ance of the trabeculum as well as that of the rest of the angle is in no way different from that of a nonglaucomatous eye, so that by gonioscopy the glaucomatous character of the eye in question cannot be recognized.

Excessive pigmentation of the trabeculum is usually associated with signs of pigment migration in the iris and all over the anterior chamber. Gonioscopy has failed to produce any new evidence in favor of the pigment-block theory or to shed light on the finer mechanism of this quasi-type of glaucoma. The fact is disturbing that in the many cases of capsular exfoliation without glaucoma excessive trabecular pigmentation is the rule.

How difficult it is to estimate the permeability of the trabeculum from its gonioscopic appearance is well illustrated by the many cases of chronic anterior uveitis in which pigmented and unpigmented débris is deposited on and within the trabeculum. There is no apparent parallelism between the intensity of these deposits and the incidence, course, and severity of the secondary glaucoma that develops in some of these cases. Again from the gonioscopic picture of trabecular changes alone one cannot tell to what extent the balance of the intraocular pressure has been or will be disturbed. In the rare type of recurrent mild cyclitis with elevation of tension at the first and each subsequent attack during which the gonioscopic picture remains perfectly normal, it appears certain that trabecular impermeability or angle obstruction of any kind plays no part at all. This is just another example of a mechanism producing a glaucomatous state which is associated with a normal gonioscopic appearance of the trabeculum.

There is a field where gonioscopy shines; that is, the examination of the sites of anti-glaucomatous operations. After trephining or iris-incarcerations in which the site of the operation is not completely concealed by adhesions between the

iris and the anterior wound lip, gonioscopic examination affords an excellent view of the area of operation and usually a simple explanation of its failure or success. The success of both, the trephining as well as the iridencleisis, depends upon the permanent patency of the operative wound or defect. In most permanently and unconditionally successful iridencleises, a portion of the incision is kept open by the interposition of iris in one or both corners of the wound, the iris acting not as a wick but to keep the wound lips separated. Thus, in slight deviation from Sugar's idea, we are inclined to think that a sclerectomy, if added to the iridencleisis, should be made in the portion of the incision that is not taken up by the incarcerated iris. This technique would seem to give the best chance for permanent gaping of the incision. Proliferation of retinal pigment, starting from the incarcerated-iris portion, is usually fairly pronounced, but rarely sufficient to cause late closure of the operative gap. Among the cases without visible gap of the surgical incision there were permanent successes, apparently through wick-action of the incarcerated iris. More commonly, however, the intraocular pressure did not remain within normal limits and miotics had to be used. In trephining, the conditions for permanent patency of the corneoscleral defect are ideal if uveal tissue or lens is entirely absent from its rim or lumen. The greater the portion of the circumference of the hole that is lined by uveal tissue the less chance there is of permanent patency. In order to avoid these adhesions, the site of the trephining should be well outside of the area covered by the PAS, and the postoperative contact between iris and cornea should be reduced to a minimum. A trephine opening may become closed by proliferative or scarifying processes in the subconjunctival space ("from the outside in"). While gonioscopy cannot be expected to give

information concerning these processes, it explains why the operation failed in most cases in which the dissection had been carried into the stroma of the cornea, beyond the rim of Bowman's membrane. There gonioscopy reveals that the outer covering of the trephine hole, although it is directly exposed to the intraocular fluid, does not become pliable enough to form part of a bleb or even to remain detached from the remainder of the cornea.

That a successful cyclodialysis is associated with the gonioscopic picture of a permanent supraciliary cleft leading into the suprachoroidal space is now generally known. That the cleft and not an "atrophy" of the dialyzed portion of the ciliary body is the actual pressure-reducing principle is clearly demonstrated by the recurrence of hypertension if the cleft closes up. The actual depth of these "pockets" is sometimes difficult to determine, nor are the factors well understood which favor or hinder the permanent patency of the pocket.

Sugar's statement¹⁰ that "most failures of well-performed cyclodialysis operations are due to the persistence and organization of a blood clot in the aperture of the cyclodialysis cleft" is unquestionably correct. The presence of blood or fibrin in the pocket two weeks postoperatively is an unfavorable sign, although complete absorption of such clots without closure of the pocket has been observed. We have the feeling that in the operative failures bleeding into the pocket has continued for some time or recurred several times. Electro-coagulation of the anterior ciliary arteries in the region of the cyclodialysis immediately before the latter may be of value to reduce the danger of severe hemorrhages. From purely clinical analysis, cyclodialyses made in the upper half of the globe have a better chance of remaining open than do cyclodialyses made in the lower half. Late closure apparently occurs more often in eyes in which the

original pocket was narrow in meridional direction. Thus eyes with very shallow chambers appear to be less favorable subjects for cyclodialysis than eyes with deep anterior chambers. This point has been emphasized by Bangerter and Goldmann,¹ who apparently have used cyclodialyses more widely than ophthalmologists in any other large clinic. For the reason that the upper portion of the angle is usually the narrowest, Bangerter and Goldmann prefer to make the cyclodialyses temporally, in a location avoided by Sugar because of the danger of injury to the long posterior ciliary artery. Since this artery enters the ciliary body in the posterior portion of the orbiculus, a cyclodialysis can be performed temporally without injury to the artery. Bangerter and Goldmann contend that in the presence of a very narrow angle an iridectomy prior to the cyclodialysis improves the chances for a permanent patency of the latter. The available gonioscopic evidence is equivocal with regard to the effect of preëxistent PAS upon the permanent patency of a cyclodialysis pocket; although it would seem logical that, in an angle sector that is free of PAS, a cyclodialysis can be performed with greater ease and less trauma than in a sector closed off by PAS.

SUMMARY

The present status of gonioscopy may be summed up by listing some of its plus as well as its minus values.

Plus values of gonioscopy: 1. Gonioscopy offers a simple mechanical explanation for certain glaucomas. 2. Gonioscopy helps choose the type of operation most suitable for the case under consideration. 3. Gonioscopy helps recognize the causes of failure of glaucoma operations. 4. The information obtained by gonioscopy is of prognostic value in that it enables us to tell whether or not a filtering operation will continue to function. 5. The information obtained by gonioscopy may be of

value in inflammatory and traumatic diseases of the eye.

Minus values of gonioscopy: 1. Gonioscopy offers no explanation of the mechanism of certain glaucomas. 2. Gonioscopy requires some special equipment. From 2 to 4 hours are required to learn

the technique of gonioscopy. Considerable experience is required to interpret cases in which the landmarks have been obliterated. 3. Gonioscopy is conducive to the development of an over-mechanical concept of glaucoma.

TORSION IN PERSONS WITH NO KNOWN EYE DEFECT*

THOMAS G. HERMANS

Seattle, Washington

From the numerous experiments that have been performed on the problem of torsion throughout the last 100 years, there has emerged no clear understanding or agreement among current authoritative sources. Physiologists hold that through the combined action of the external muscles of the eyeballs torsion does not occur; whereas ophthalmologists tend to regard it as abnormal. Starling,¹ Best and Taylor,² Howell,³ and MacLeod,⁴ either state specifically or imply that torsion does not occur. Ames and Gliddon⁵ report from the Dartmouth Medical School measurement of cyclophoria (torsion) in clinical patients "suffering more or less acutely from their eyes." They speak of "cyclodeclination condition," "cyclotor-

sional trouble," "abnormal cyclotorsional condition," and "suffering from cyclo-diplopia" as if torsion were an abnormality of vision, yet they apparently have no facts as to what normal persons, or non-clinical subjects, might show in the way of torsion. They would probably admit as does Duke-Elder⁶ that a "certain amount" of torsion might be normal. For the purpose of establishing this "certain amount" the experiment herein to be reported was performed. Carow⁷ is the only individual found working on the problem who seemed to realize the importance of measuring torsion in large numbers of pathologic cases. He measured torsion in 107 employees of a Berlin police station. Most of his subjects had eye defects of one kind or another, but at least they were not recruited from clinics; only 14 subjects yielded what he regarded as good data. His analysis of the data consisted only of the calculation of averages.

* From the Department of Psychology. University of Washington. A résumé prepared by the author of his much more detailed paper, which appeared in the Jour. Exp. Psychol., 1943, v. 32, April, no. 4, pp. 307-324.

From the foregoing considerations it seemed advisable to measure torsion in persons with no known eye defect in an attempt to answer the following questions: 1. Is torsion a normal or an abnormal phenomenon? 2. If it occurs in normal vision, what direction of torsion may be expected? 3. What is the average amount that might be expected? 4. What is the normal variability that might be expected from one person to the next? 5. Does it vary with variation in elevation of vision above and below horizontal? 6. Does it vary with changes in convergence? 7. Are the torsional movements bilaterally symmetrical for the two eyes? 8. What are the torsional changes with oblique and lateral fixation points in the visual field? 9. Is it a source of distress in vision? The following report of experimental procedure and the results obtained is an attempt to answer all but the last three of these questions.

Three essentially different methods of testing torsion have been used. Some of the conflicting statements about torsion arise as an artefact of the method used. One method frequently cited uses the afterimage. However, only the monocular afterimage may yield valid results. The binocular afterimage would not show validly the torsion in either one or both eyes, owing to the fact that a binocularly fixated point or figure, seen as single during fixation, never produces a double afterimage; the perceived position of the afterimage tends to remain a function of the positional relationships maintained during retinal fatigue. Statements by Starling,¹ Duke-Elder,⁶ and Tscherning⁸ are invalidated by the fact that they are based upon the use of the binocular afterimage.

A second method is that of observing directly torsion by use of a telescope with vernier scale, the cross-hairs of which can be superimposed on distinctive markings of the iris. This method is recommended

for its objectivity. However, with the telescope used by Loring⁹ in the local laboratory I found it difficult to discriminate with any degree of certainty changes of less than a degree. Moreover, Loring reports that pupillary changes even with constant illumination made it difficult at times to identify the distinctive marking previously sighted.

A third method of measuring torsion is

Fig. 1 (Hermans). Figures of the "Volkman disc" type for binocular fusion.

that of presenting to the two eyes separate figures that are binocularly fused by means of some stereoscopic device when their angular rotations on the visual axes are in proper relationship. The type of figures or targets commonly used is what has come to be known as "Volkman's discs." These are circles set at right angles to the visual axes with the centers as points of fixation; a radius is drawn on each circle, but on opposite sides of the centers, so that when one or both discs are properly rotated the radii become an apparent diameter of the circle (fig. 1). If diameters are drawn on the two circles the subject then has to discriminate when the lines are perfectly superimposed; they must fixate some point on the line and tell when there is no apparent doubling of the lines peripheral to the point of fixation. Such discrimination of double images is difficult for the naïve subject and may give unreliable results. The use of targets by Ames and Gliddon,⁵ requiring peripheral discrimination of double images, plausibly accounts for their incredible report that "Usually the declination of

the vertical meridians is greater than that of the horizontal."

From a careful consideration of the various methods of measuring torsion, it seemed advisable for the present study to use the stereoscopic technique with targets of the Volkman disc type. They were circles 1 inch in diameter; projecting 4½ inches beyond the circles were bars one-eighth inch wide; with one circle the bar projected downward and with the other

upward. In effect, these targets combined binocularly as radii of a circle 10 inches in diameter. With a system of mirrors known as a telestereoscope changes in convergence could be effected. Changes in elevation of vision were made possible by rotation of the apparatus vertically about an axis approximating the center of rotation of the subject's eyeballs. The subjects rotated the targets synchronously in opposite directions until the bars appeared to

make one continuous straight line through the stereoscopically fused circle. Their adjustment of the targets could be read to one tenth of a degree.

The subjects used in the experiment were 104 naval R.O.T.C. students who had had recent eye examinations and had

Readings were taken only to 10 degrees of convergence; incidentally, this refers to the angular change in each eye.

A distribution of the subjects' judgments for each of the 99 combinations of convergence and elevation was made, and the average and standard deviation from

Fig. 2 (Hermans). Obtained average values of torsion plotted against the two variables, convergence and elevation of vision.

been passed as "normal"; that is, with 20/20 vision and no detected visual defect. Readings of the subject's adjustment of the targets were taken at as many combinations of elevation and convergence as the subject was able to maintain binocular fusion of the targets. A few subjects found it impossible to fuse the targets with parallel axes of vision, and every one would reach some point of convergence beyond which fusion was impossible.

the average calculated for each distribution. The values derived from these calculations are given in the accompanying table; the horizontal variable represents degrees of convergence, the vertical variable, the degrees of elevation of vision above and below horizontal. The first item in each cell of the table indicates the number of subjects able to make judgments at this combination of the two variables. The second item is the average

value of the subjects' adjustment of the targets. The direction of rotation of the targets is a tipping of the vertical diameters of the fused circles of the targets away from each other at their tops. Correspondingly, the rotary direction of the eyes is that which would result from unopposed contraction of the inferior

disinclination of the upper ends of the vertical meridians of the eyes from the medial plane. The two exceptions are indicated by the minus sign. The third item in each cell is the standard deviation from the average of the obtained values. This is a measure of the variability of subjects and defines the limits on either side of

Fig. 3 (Hermans). Theoretical values of torsion plotted against the two variables, convergence and elevation of vision.

oblique muscles. For simplicity in speaking of torsion we shall assume that these figures refer to torsion of the eyes; for obviously, the eyes have undergone torsion of these amounts and the targets have had to be rotated in the same amount and direction to meet the subject's requirements for judgments of straight lines. The direction of the torsion indicated (with two exceptions) is an ex-torsion or

the average within which the middle 68 percent of the torsion values were found. To illustrate, 104 subjects made judgments with vision horizontal and with 2 degrees of convergence; the average judgment was .23 degrees, and standard deviation .38 degrees; 68 percent of their judgments were between .23 - .38 and .23 + .38 or between -.15 and +.61 degrees; the remaining 32 percent of sub-

jects made judgments that deviated more than .38 degrees from the average. The fourth item in each cell is the theoretical average; how this was obtained will be explained later.

Figure 2 shows the three-dimensional surface obtained when the average values of torsion in degrees are plotted against degrees of elevation and degrees of convergence. The striking appearance of regularity of this surface suggests the desirability of obtaining an equation descriptive of the relationship between the three variables. Theoretically, the surface would be entirely smooth if a large enough number of subjects had been used. On this assumption calculations were made and the following equation derived:

$$Z = +.00573x^2 + .00001y^2 + .00148xy + .07029x + .0028y + .06876$$

Z represents degrees of torsion, x degrees of convergence, and y elevation of vision in degrees above (plus) or below (minus) horizontal.

Using this equation, theoretical values of torsion were calculated for the 99 points of the graph. The fourth item in each cell of the table is this theoretical

value. Figure 3 shows this smoothed surface. To illustrate how closely the two surfaces coincide it should be pointed out that the standard deviation of the differences between the obtained and theoretical averages is .13 degrees; that is, 68 percent of the theoretical values of torsion are within .13 degrees of the obtained values.

In conclusion, torsion has been shown to be a normal phenomenon of vision. The direction of torsion to be expected is a disclination at the top of the vertical meridians of the eyes relative to the medial plane, except at extreme positions of elevation below horizontal and with a small amount of convergence; in this position the torsion is reversed. The average amount of torsion to be expected for any combination of convergence and elevation is expressed by the above equation; this may be regarded as a law descriptive of eye-movement. The amount of variability in torsion that one might expect in individual cases, and still be regarded as normal, is expressed best by the various standard deviations from the average values as indicated in the table.

HIGH CONGENITAL MYOPIA WITH CONVERGENT STRABISMUS*

RICHARD C. GAMBLE, M.D.
Chicago

In 1930, a child, 22 months of age, was referred to me for examination because the eyes had a definite tendency to cross when looking at close objects. The refraction, measured with the eyes under the effect of atropine, showed 16D. of myopia in each eye and, much to my surprise, the convergent squint completely and immediately disappeared as soon as the child was provided with glasses. This unusual experience prompted a reasonably thorough review of the literature on similar cases. All that one could find was a case report here and there of an infant with a high degree of myopia, but no mention of any strabismus and, most important of all, no observations over a period of years to give one any idea of what to expect in regard to the visual prognosis for children having this defect.

Many questions presented themselves. What was the cause of the strabismus, and why was it corrected by concave lenses? Was this myopia really congenital, owing to the lens being more spherical than usual, or was it axial? Do such cases progress and ultimately result in the extremely high myopia with marked retinal destruction that we see at times? This study is an attempt to answer these questions.

In the past 13 years, 25 children have been examined who had what can reasonably be called high congenital myopia. An arbitrary standard of five diopters of myopia before school age has been adhered to with a few exceptions. Myopia associated with obvious microphthalmos or ectopia lentis has not been included nor have cases of monocular myopia. Refractions have been repeated as often as

indicated. In five of the patients the refraction was measured only once, so these are not included in the figures showing changes in the amount of myopia.

The following table shows most of the facts revealed by this study:

TABLE 1
HIGH CONGENITAL MYOPIA WITH CONVERGENT STRABISMUS—SHOWING AMOUNT OF MYOPIA, RATE OF PROGRESS, AND FREQUENCY OF STRABISMUS

Number of patients with high congenital myopia.....	25
Number of patients refracted more than once.....	20
Average age at first examination..	4.3 years
Average amount of myopia at first examination.....	-10.45D.
(Max. -16.50; Min. -4.50)	
Average age at last examination..	8.8 years
Average amount of myopia at last examination.....	10.88D
Average period of observation...	4.1 years
Average change in refraction per year.....	-.18D
Number of eyes becoming more myopic (total 40).....	19
Number of eyes becoming less myopic (total 40).....	15
Number of eyes showing no change of refraction (total 40).....	6
Number of patients with convergent strabismus.....	15
(All recovered except two, in one the squint became divergent later)	
Number of patients with divergent strabismus.....	1

The high incidence of convergent strabismus is remarkable. In one case the deviation was 35 degrees, in all of the others the deviation was only 10 to 20 degrees, and in many cases it was not constant. The fact that it was of low degree and usually was corrected immediately by the use of glasses suggests the possibility that it was a physiologic condition related to the fact that the far point was so close to the child's eyes. It might be assumed that, inasmuch as everything more than 10 cm. away is indis-

* Read before the Chicago Ophthalmological Society, March 15, 1943.

tinct in a case of myopia of 10D., the child makes his binocular adjustment for close objects only. Some of the facts are not in accord with this simple explanation, however. There were a few cases in which amblyopia of moderate degree could be demonstrated when the child became old enough to have suitable tests made, and in several cases fusion and stereopsis were subnormal. One child had a convergent strabismus of 20 degrees and myopia of 12D. at three years of age; the strabismus was corrected immediately by the glasses, but at the age of 11 years she developed divergence excess with 18 degrees of exotropia for distance. She had vision with glasses: R. 20/25, L. 20/15 and had good fusion and stereopsis.

It is quite obvious that this type of myopia is different in many ways from the usual axial type that begins in the early school years, increases during the years of growth, and then becomes more or less stabilized. The very slow average rate of increase ($-0.18D.$ per year) in this series is very gratifying. These children have all been able to make satisfactory progress in school, most of them in regular school, a few in sight-saving classes, and it does not appear that the work has harmed their eyes. A myopic conus was observed in only two patients, one with 10D. of myopia and one with 15D. Other patients with just as much myopia did not have a conus nor any myopic retinal changes. In no case did the eyes appear abnormally larger or protruding; in fact, the opposite was usually the case. We are all familiar with myopia in cases of microphthalmos and ectopia lentis where the anteroposterior diameter of the globe is not abnormally great. The lack of stretching of the posterior seg-

ment of the eye and the very slow rate of increase in myopia in these congenital cases strongly suggest the possibility that the cause of the myopia is due to the lens being abnormally spherical. This assumption is in agreement with what is well known regarding the development of the infant eye. Measurements have shown that the lens of a normal eye of an infant has twice as great a curvature as in the adult. The reason this condition of the lens does not always result in the infantile eye's being myopic is that it is usually more than compensated for by the short anteroposterior diameter of the eyeball at birth. Congenital myopia will be present if the anteroposterior diameter is not short enough to compensate for the myopia owing to excessive curvature of the lens. Such myopia may decrease as the lens becomes less spherical with age unless this is offset by an increase in the anteroposterior diameter, or it may increase if the anteroposterior diameter becomes greater at a more rapid rate than is compensated for by the change in the lens. In this series the two processes apparently took place at about the same rate, so there was no marked change in the refraction.

CONCLUSIONS

1. High congenital myopia and convergent strabismus are often associated.
2. The myopia is lenticular in origin and relatively nonprogressive, at least up to the age of adolescence.
3. The convergent strabismus is of low degree, is usually corrected by glasses, and is, on the whole, relatively unimportant.

30 North Michigan Avenue.

DISCUSSION

DR. WILLIAM F. MONCREIFF: Dr. Gamble's paper presents two separate and

distinct problems: first, that of congenital myopia as an etiologic factor in con-

vergent squint; second, that of the pathogenesis of congenital myopia. These two problems would appear not to be closely related, their juxtaposition in the paper being accounted for by the circumstance that in some 60 percent of the cases of congenital myopia reported, a convergent position of the eyes was observed, tabulated as convergent strabismus.

As to the role of congenital myopia as a causative factor in convergent strabismus, Dr. Gamble's remark that a child with congenital myopia of 10D. makes his binocular adjustment for close objects only, is in accord with the observations of Chavasse, who pointed out that the extreme nearness of the far point, varying from less than 6 cm. to an average of not more than 10 cm. requires such a high angle of convergence for the development of binocular single vision, that with its development must come more or less strong esophoria; this, if prolonged for a sufficient time, may be finally transformed into esotropia.

One may question whether the convergent position of the eyes observed in 15 of these congenitally myopic patients was in every instance a true esotropia. Convergence of the visual axes on near objects, to the meter angle equivalent of the distance, is a physiologic fact and necessary for binocular single vision; also, the term esotropia, or convergent strabismus, does not apply unless the convergence exists when fixating an object at a distance of 6 meters or more. How can one correlate or compare the observed angle of convergence with that appropriate to the distance of fixation when there is no accurate means of determining what the fixation distance is? Furthermore, how can an infant or child with 5 to 18D. of myopia, uncorrected by lenses, fixate an object at a distance of 6 meters which he cannot even see? The fact that convergence disappeared promptly in many

cases with the application of correcting lenses adds further to the suspicion that the convergence was not that of a true esotropia.

In the nine patients in whom no convergence was observed there was an average of 10D. of myopia or more; in one case the myopia was as high as that of any other patient in the entire series. In the majority of these cases the difference in refraction between the two eyes was at one time or another only one diopter or less, and, in most of the cases, correcting lenses were first applied in the fourth year or younger. Could it be that within the limits of the far point, those with about equal myopia in the two eyes developed sufficiently good stereopsis to prevent the occurrence of esotropia? Some of the others perhaps did not begin to exercise their visual faculties to any marked extent on near objects and small details prior to the first correction of the refraction.

The essayist noted the presence of amblyopia and defects of stereopsis in certain cases in which a true strabismus persisted beyond the age of six years. Further analysis of details not reported in the paper might show the cause to be high astigmatism in one eye only, or much higher myopia in one eye than in its fellow.

As to the pathogenesis of congenital myopia, the essayist states that this is lenticular in origin. No proof of this conclusion is offered, but the idea is apparently adopted as an alternative to the more tenable one of an axial myopia. He rejects axial myopia as an explanation because (1) choroidal, retinal, and other fundus changes observed in high myopia in many adults were not present; (2) there was no significant increase in the amount of myopia in any case, and even a decrease in some cases. The first consideration is untenable; it is well known

that, with the exception of a simple conus (malformation) due to obliquity of the optic-nerve-entrance canal, these other fundus changes require some years for development, and, as a rule, are not to be seen in infants or even older children until beyond the age of puberty. The second consideration has no significance, owing to the complexity of changes occurring in the early years of growth and affecting all the factors which determine the refraction of the eye.

The three most essential factors that determine the static refraction of any nonaphakic eye are the cornea, the lens, and the axial length of the eyeball. The most variable of these in the newborn and in the developing infant, as regards their effect on total refraction, are, in all probability, the cornea and the length of the eyeball. Variations between different individuals in the size, curvature, index of refraction, and in general the refractive power of the lens of the infant or newborn are probably too small to account for anything more than a diopter or two of variation from the norm in refraction.

In the present state of our knowledge, according to such authorities as Vogt, Scheerer, von Szily, Seefelder, Wessely, and Schnabel, it may be said that congenital myopia is due to anomalous development of the eye in the anterior segment or the posterior segment or both. There may be a so-called refractive myopia, due not to a higher-than-usual refractivity of the lens, but to increased refractive power of the cornea, which has a shortened radius of curvature. This is sometimes combined with a greater-than-average diameter of the base of the cornea. An axial diameter of the eyeball of the newborn sufficiently in excess of the

normal 17.5 mm. to produce 5 to 15D. or more of congenital myopia, is a mild grade of malformation due to limited overgrowth of the neural ectoderm of the secondary optic vesicle, which, in many cases, may be confined to the posterior half of the eyeball, but in others may predominate as an overgrowth of the ciliary zone, from limbus to ora serrata.

DR. ROBERT VON DER HEYDT: This paper gives good reasons for the convergence, its immediate correction by the strong minus glasses, and the high myopia as being due to the lens, which is quite spherical in some very young children. Children born with high lenticular myopia need not necessarily later develop progressive myopia; this is a quite separate hereditary fate.

Dr. Moncreiff apparently agreed with Dr. Gamble except for differentiating between myopia of corneal origin and that of lens origin. Both essayist and discussor should be congratulated on presenting the problem so lucidly.

DR. RICHARD C. GAMBLE (closing): In regard to the first point brought up, Dr. Moncreiff seems to be even more inclined to the idea of physiologic convergence than I am. As to the second point, Dr. Moncreiff has studied sections of infants' eyes and is well aware of the fact that the lens in an infant's eye is more spherical than it is in the adult. It is hard to understand why he does not consider this fact important.

Dr. Von der Heydt in his long experience has apparently observed some of the things described in this paper, and it is gratifying to hear him say so. He himself has had to find them out by watching the patients as they grew up.

ROBERT VON DER HEYDT.

COATS'S DISEASE

JOSEPH LAVAL, M.D.
New York

Through the courtesy of Dr. David H. Webster, I am able to present the pathologic findings in a case of Coats's disease. The history of the case as given by Dr. Webster follows:

"I first saw R. P. on September 9, 1941. The mother stated that the right eye was

muscle exercises. The patient is now 10 years of age. When I saw her she had a head tilt, ptosis of the right lid, and extreme photophobia; the eyeball appeared shrunken; vision was 1/200 in the lower field. The slitlamp showed new blood vessels in the iris; the latter was pushed

Fig. 1 (Laval). The involved area occupies all the layers of the retina. Note the adhesion of the iris to the posterior layers of the cornea with resultant closure of the filtration angle. The ciliary body is not involved.

closed at birth, and that at three months of age a convergent squint was first noticed. When the child was $7\frac{1}{2}$ years old the muscles of the right eye were operated upon for the correction of this deformity, and at the age of $8\frac{1}{2}$ years a further attempt was made to correct it. Following that she tried occlusion and

forward against the cornea in the region of the 7-o'clock position. The ophthalmoscope showed massive exudative retinitis with plaques of pigment; transillumination was difficult. A diagnosis of Coats's disease was made. The eye was removed on September 29th on account of extreme photophobia and constant headaches."

The gross and microscopic findings are as follows:

The eyeball is normal in size and shape. In the lower portion of the retina anteriorly is a small raised mass extending toward the vitreous and reaching from the ciliary body toward the equator (fig. 1). The ciliary body is not involved. Most

and free pigment lying in the filtration angle. The mass in the retina is cellular and contains cells having deeply staining nuclei which are round cells, but most of the cells are fibroblasts with spindle-shaped nuclei. There is much connective tissue (fig. 2). Occasional vessels are present in the mass and round cells en-

Fig. 2 (Laval). Marked connective-tissue proliferation. The arrow points to albuminous fluid between the choroid and the mass. Two drusen of the lamina vitrea can be seen below the arrow. To the left of the center is seen a dense mass of pigment. (Low power.)

of the mass is in close apposition to the choroid, but a small part of it posteriorly is lifted away from the choroid by albuminous fluid. The filtration angle is occluded by the iris, which is adherent to the cornea below. Microscopically it is seen that there is marked proliferation of pigment on the anterior surface of the iris with a moderate increase in round cells

velop these vessels. Clumps of pigment are present and proliferation of the pigment epithelium is moderate. In the inner layers the blood vessels of the retina are preserved, but the walls are thickened. The inner limiting membrane of the retina is intact. In the outer layers, the rods and cones are completely destroyed, and here some goblet cells are seen, which may

be swollen cells of the destroyed rods and cones (fig. 3). The other nuclear layers of the retina are gone, and in their place are connective tissue, round cells, and fibroblasts with clumps of pigment. The choroid is partly involved but in other places is intact, with fluid between it and the retina. Here the lamina vitrea is swol-

majority of the patients presented by other writers were between 2 and 19 years of age; the majority were also males. The condition is found rarely in patients over 25 years of age, and was once reported in a child of 10 months.²

According to Coats's original concept the lesion is primarily vascular and

Fig. 3 (Laval). High power, showing goblet cells or "ghost cells."

len into drusen with pigment epithelium overlying them. Prepared with the Wilder stain it is seen that the mass is predominantly connective tissue with moderate vascularization.

COMMENT

Coats's¹ original presentation consisted of 11 cases, 4 of which were in females and 7 in males. Of these 11, 5 were in patients between the ages of 6 and 8 years; 1 patient was 12 years old, and 5 were between 26 and 37 years old. The

hemorrhagic. The proliferation of neuroglia that takes place and that is so profuse at times as to give the appearance of a veritable tumor is only secondary. Retinal detachment, proliferation of pigment epithelium, and new-formed connective tissue follow later. Leber,³ however, considers the lesion as essentially inflammatory and necrotic; following the inflammation, there ensues necrosis of the retinal tissues, desquamation of the pigment epithelium, and formation of hemorrhages and exudates. The picture is vari-

able, so that in some cases vascular and hemorrhagic features are pronounced whereas in others these factors are minimal, and inflammatory exudation and organization are more prominent. The choroid is usually not involved but may at times be involved secondarily. The retina in the affected area is extremely degenerated and almost completely replaced by fibrous tissue; the vessels are sclerosed, and glial tissue proliferates to varying degrees with destruction of the neural elements.

Some observers believe that the origin of the vascular lesions is infectious owing to small infected emboli; others believe the origin to be tuberculous. In some cases the angiomatous formations are so large that some consider the original lesion to be the aneurysmal dilatation with angiomatous formations which finally cause exudative changes in the retina with detachment. (This latter, however, is really Hippell⁴-Lindau's disease and does not belong to the group designated Coats's disease.)

Coste⁵ in 1938 reviewed the entire literature and found that 29 cases had been reported in males and 22 in females, making a total of 51 up to that time; he included 2 cases of his own. His bibliography is quite complete. Lamb⁶ in 1938 also reviewed the literature and added eight cases. He concluded that the "essential change is an infiltration of the retina in whole or in part with albuminous and edematous fluids, leading to an exudate of the same fluids under the retina and a resulting complete or partial detachment of the retina. The . . . late cases are further distinguished by the presence of large amounts of connective tissue between the choroid and the retina or in the retina." He further states that the exudative process is diffuse throughout the retina and not only in the external layers as Coats found it. He agrees, however, that an inflammatory process is pres-

ent and for that reason agrees with Coats's later concept of "exudative retinitis." Lamb makes the point that the pigmented epithelial cells of the retina become macrophages and then are transformed into fibroblasts. These then proliferate and lay down the dense masses of connective tissue found in cases of Coats's disease. Clinically, there are large yellowish-white masses of exudate in the fundus, lying under the retinal vessels which may be obscured in places, however. Most commonly these masses are at the posterior pole but not uncommonly they are in the periphery. Hemorrhages are frequently present and often cholesterol-like glistening deposits are seen. The vessels may be tortuous or looped, or even occasional anastomoses may be present. Detached retina, glaucoma, iridocyclitis may ensue; in other cases the process goes just so far and then remains stationary, while in some a pseudogliomatous mass may be formed.

An interesting paper by Holm,⁷ published in Copenhagen, in 1941, makes the point that there is a great similarity between Coats's disease and retinitis circinata and also macular proliferation both of the senile and juvenile types. In studying the pathology of these various conditions one is struck by the great similarity and also by the overlapping of the fundus pictures as seen clinically. In Duke-Elder's text book are compiled all the views and reports of different observers of the accepted pathologic pictures of these allied conditions.

Summarizing then, it may be stated that Coats's disease and circinate retinopathy depend primarily on changes in the retinal arterial system, whereas senile and juvenile macular degeneration are the result of changes in the choriocapillaris.

POSTOPERATIVE ENDOGENOUS INFECTION OF THE EYE WITH RECOVERY

REPORT OF TWO CASES

DANIEL KRAVITZ, M.D.

Brooklyn, New York

AND

LLOYD J. DUEST, M.D.

New Bedford, Massachusetts

Postoperative infections of the eye may be ectogenous or endogenous. In the first instance, infection shows itself 24 to 48 hours following an operation, usually cataract extraction.

The first sign is a grayish edema of the cornea around the incision and edema of the nearby conjunctiva. The infection has a tendency to spread rapidly and soon a hypopyon makes its appearance. Shortly the entire cornea becomes hazy, the conjunctiva greatly chemotic, and, before long, the vitreous is invaded. Usually there is an outpouring of purulent material through the wound of the cornea. In the majority of cases the eye requires enucleation or it eventually shrinks to an extreme degree.

According to Fuchs,¹ endogenous infections are usually the result of septic emboli thrown off by septic foci, invading a local point made less resistant as a result of trauma (operation), in the same way that an osteomyelitis may involve bone at the point of local injury. The condition, while it occurs occasionally

in an eye which has been operated upon under the best possible circumstances (asepsis, operative technique, and the like), is thought to occur more frequently if there has been excessive ocular manipulation.

This type of infection usually shows itself on the fifth or sixth day following an operation, though a much earlier appearance has been reported.² The initial reaction is not apt to be so virulent. There is some clouding of the cornea, moderate circumciliary reaction, and a small amount of hypopyon. As the infection progresses, the hypopyon increases and the reaction of the eye becomes more severe. Soon the eye takes on the same serious appearance that follows exogenous infection and with the same results.

Occasionally the infection is not so fulminating and it may subside, leaving a dense plastic exudate in the anterior chamber and usually in the vitreous chamber as well. These exudates shrink and result in phthisis bulbi. Rarely, however, the eye itself may be spared serious

damage and only a dense membrane in the anterior chamber be the final result. When this is cut the eye may regain useful vision.

Fortunately, postoperative endogenous infection is not common—in spite of the impossibility of eradicating all foci of infection, often because the eye itself has become the focal point of infection.² For this reason two cases in which good results were obtained in spite of severe postoperative infections are deemed worthy of report.

Case 1. T. S., a man, aged 81 years, came to the office (of D. K.) on January 4, 1943, because of progressive loss of vision for the past year. At present vision was so poor that he had to be led around. He had had diabetes for many years. About seven weeks prior to this visit he had developed an acidosis and was taken to a hospital where he remained for six weeks. During his stay at the hospital he lost 40 lbs. in weight and his diabetic condition was brought under control.

Examination revealed an almost mature cataract in the right eye and a mature cataract in the left eye.

The patient was admitted to the Brooklyn Eye and Ear Hospital for extraction of the lens of the left eye on January 5, 1943. A preoperative smear was negative for pathogenic organisms. On the same day, an attempt at an intracapsular extraction was made, but the lens could not be dislocated. The capsule was then incised with the cystitome and the lens expressed. Additional cortex was removed by irrigation. The wound was closed with two corneoscleral sutures, at the 2- and 10-o'clock positions. At the first dressing, two days later, the eye was white. On January 8, 1943, the eye was white and there was a small amount of cortex present. That night the patient was found under the bed, but the dressings were in

place. On January 9th, a small amount of conjunctival secretion was observed. The eye was uncovered and sodium sulfathiazole solution, 5 percent every two hours, was instilled. The patient also was allowed out of bed.

On January 10th, the conjunctival secretion had disappeared, but the cornea around the lips of the wound was somewhat hazy and there was a slight amount of hypopyon in the lower anterior chamber. The eye was moderately injected. Sulfadiazine, gr. 15 every four hours for six doses, was ordered to be followed every four hours by gr. 7ss. of the drug. Two tablets of abdol, vitamin tablets, three times daily were also prescribed. On January 11th, the hypopyon did not seem greater and the eye appeared about the same. The next day, the hypopyon had increased to fill about half of the anterior chamber, and the eye felt soft to digital pressure. By the 14th, the anterior chamber was about three-fourths full with hypopyon and in addition there was an exudate in the upper part of the anterior chamber near the corneal section. Following this day the hypopyon seemed to decrease steadily. The patient refused to stay in the Hospital and was discharged on the 19th of January with a note that there was still an abundant amount of exudate in the anterior chamber but that it seemed to be receding. There was only a moderate amount of reaction in the eye.

During his stay at the Hospital the patient received a diet consisting of carbohydrates 150, proteins 60, and fats 110 gm. He also received 20 units of protamine zinc insulin before breakfast.

The patient was kept on sulfadiazine for a week after leaving the Hospital. The hypopyon kept receding, and a tendency to membrane formation was noted, so that by April, 1943, the eye was entirely white, and there was a dense mem-

brane extending from the lower pupillary border to the corneal section.

The patient was again entered at the Brooklyn Eye and Ear Hospital on April 29th, where a deWecker discission was performed. On May 24th, vision was 20/40 plus with a +11.00D. sph. \approx +2.00D. cyl, ax. 160°, and these glasses were prescribed.

Case 2. A. M., a man, age 74 years, was admitted to the Brooklyn Eye and Ear Hospital from the out-patient service of Dr. Hargitt, on October 5, 1943, with a mature cataract in the right eye.

Physical examination revealed a soft systolic murmur at the aortic area, a blood pressure of 140/80, deeply stained but noncarious teeth, and an aphakic left eye. The blood Wassermann and urine examinations were negative for pathologic changes, and the smear from the eye taken before the operation was negative for pathogenic organisms.

Preoperative procedure was carried out according to the Bell technique. O'Brien block and retrobulbar injections were given and an ample section was made. As the section was completed there was a slight bulging forward of the iris. It was thought, however, that this was not of such degree as to contraindicate extraction by the intracapsular method.

An iridectomy was done, the lens capsule was grasped at the lower pole, and slight pressure was exerted just inside the limbus in order to dislocate the lens. This maneuver was about completed when vitreous began to present. The intracapsular technique was then abandoned and the capsule ruptured with the cystitome. In attempting to remove the lens by pressure and counterpressure, the lens was dislocated into the vitreous chamber. The lens was spooned out with the Weber loop and although more vitreous was lost, the total amount was not excessive.

Three conjunctival sutures, previously

prepared, were tied, no attempt being made to replace the iris pillars. A large air bubble remained in the anterior chamber. Atropine 1 percent, and metaphen 1:2,500 were instilled.

With the possible exception of the persistent air bubble in the anterior chamber, the postoperative appearance of the eye was not unusual until the fifth day. At this time it was noted that the entire cornea was becoming opaque and there was marked hyperemia of the entire conjunctiva. A diagnosis of postoperative endophthalmitis with hyalitis was made.

The appearance of the eye became progressively worse. On the ninth day, slitlamp examination revealed the cornea to be clear, and the gross appearance of the haziness was observed to be due to a gelatinous mass of grayish-green exudate in the anterior chamber, through which the iris could not be visualized. There was a small hypopyon in the bottom of the anterior chamber. On the 12th day, a small area of exudate in the upper border of the coloboma began to separate from the iris. Following this there was rapid recession of the inflammatory condition. Slitlamp examination on the 17th day showed the cornea to be clear. The iris structures were just visible. There was a membrane across the area of the coloboma which was believed to be lens capsule, and there was a large mass of yellow-green exudate in the vitreous. This vitreous exudate was rapidly absorbed so that on the 21st day there was only a small bead attached at the equator above the vitreous. At this time the patient was able to perceive the outlines of persons in good light at one-half meter.

The patient was discharged from the Hospital on the 26th postoperative day to be subsequently followed in the out-patient department.

Examination at this time showed many

vitreous floaters which seemed to consist of strands of exudate. There still remained a small bead of exudate at the equator above the vitreous, but this was much smaller than when previously observed. A fundus reflex could be obtained, but the details could not be made out. The conjunctival injection was disappearing and white sclera was beginning to show. The patient could count fingers if they were held above so that the patient could look through the upper part of the coloboma which was free of capsule.

The patient was again seen on November 11, 1942, at which time the vitreous exudate had completely disappeared and there were fewer vitreous floaters present. With a +10.00D. sph. \approx +2.00D. cyl. ax. 105° he could distinguish features at 20 feet.

The patient was readmitted to the Hospital in April, 1943, and a discission performed. At present, except for some vitreous opacities, the fundus is negative for pathologic changes. Vision is 20/10+, and he is able to read and write.

Treatment in this case was rather vigorous in spite of the advanced age of the patient. When it was noticed, on the fifth postoperative day, that an intraocular infection was impending, an intravenous injection of 5,000,000 typhoid germs was given. This was repeated on the sixth, ninth, and eleventh days, with increasing doses of 10,000,000, 15,000,000 and 50,000,000 typhoid germs, respectively. The reactions were only moderate, the highest temperature obtained being 101.4°F.

At the same time, sulfathiazole, gr. 60 daily, was given until the 20th day. Hot compresses were started on the sixth postoperative day and were given three times daily for 20 minutes, followed by the instillation of atropine sulfate 1 percent. Two days later, the hot compresses were discontinued and infrared therapy was instituted. The lamp was used di-

rectly on the eye at a distance of 12 inches. In this way a maximum temperature was reached in eight minutes. This was sustained for 12 minutes longer.

On the 14th day, 10 c.c. of sterile milk was injected intramuscularly, and this was given daily for the next eight days.

In addition to all this, one drop of dinin 3 percent was instilled morning and night.

DISCUSSION

The two cases here reported are similar only in the fact that they were late postoperative infections, probably of endogenous origin; other than that their similarity ends.

In case 1, the operative trauma was no greater than that incident to the average cataract extraction. The second patient undoubtedly had severe operative trauma. Whether such trauma is a direct cause of infection is questionable and difficult to decide. Yet it is our impression that the percentage of infections following severe or prolonged operative trauma is not great. An iritis or an iridocyclitis is more likely to develop. However, there can be no question regarding the fact that, in such a delicate organism as the eye, excessive trauma should be avoided. Greater attention must be paid to the choice of operation, and one should change the operative procedure as the indication arises, rather than persist in carrying out a preconceived plan of operation.

In spite of the more advanced age of the first patient and the obviously poor physical condition, the infection remained confined to the anterior chamber. In the second case, on the other hand, the vitreous chamber seemed to be involved to a greater extent. At no time, according to the operator (L. J. D.) was the hypopyon more than minimal in amount. The recovery seems all the more remarkable, as rarely does such a large vitreous exu-

date become absorbed so that useful vision is obtained.

Therapy likewise was radically different in each case. In case 1, only a sulfonamide in large doses and over a prolonged period of time was given. In case 2, in addition to a sulfonamide, a large variety of measures, some of them heroic, was tried.

In the past, such heroic measures, without the use of sulfonamides, were rarely attended with success. One must therefore give credit in these cases to the sulfona-

mides for the results obtained. Ophthalmology owes a great debt to the discoverers of these valuable drugs.

An interesting sidelight on the administration of the sulfonamides is that in old people large doses and prolonged use of these drugs are extremely well tolerated. Certainly with these drugs in the armamentarium a good deal of despair is avoided if one is unfortunate enough to get a postoperative infection of the eye.

ESSENTIAL ATROPHY OF THE IRIS*

FRED MCK. RUBY, M.D.

Union City, Indiana

The present case of essential atrophy of the iris is presented for a double purpose. First the condition itself is rare enough to warrant reporting. Benedict—who with Henderson reported a case in 1940—has seen no other since the case reported by Barr and himself in 1934 (fig. 1). The second reason is that the condition was complicated by a "paper-dust" irritation of the cornea—somewhat common in packers at glass plants. The arrival at a decision as to just where the compensation stopped and the essential condition carried on presents a very nice problem.

To approach the case from its history, rather than its actual development, something should be stated about "paper-dust" irritation. During a year spent in Washington State, I had the opportunity to see many cases of "fir" poisoning. When a workman in the big mill would get a splinter in his hand or arm, especially

if of some size, the swelling in 30 minutes would be enormous. Moreover, when the worker would forget "fir" sawdust, which often became caught in the cilia

Fig. 1 (Ruby). Sketched from Henderson and Benedict's report of iris atrophy (Amer. Jour. Ophth., 1940, v. 23, p. 645).

of his nares, and would grasp his nose to "blow hard," he often showed up in 30 minutes with a purplish nose about the

* Read before the Indiana Academy of Ophthalmology and Otolaryngology, April 28, 1943.

size of a Bartlett pear, and be a sick man. Finally, when a small spicule of fir sawdust was incarcerated in the conjunctival sac or in the cornea, the swelling, epiphora, and discomfort were out of all proportion to the size of the foreign body, or its location. Many of these spic-

Fig. 2 (Ruby). The eye in the author's case—early stage, sketched from details given in the history.

ules were localized in the lid conjunctiva, upper or lower, by delicate palpation of the everted lid, not being visible by the naked eye. Removal of such particles, after being undiscovered for several days, would set up a reaction lasting as long as a week.

Now the pulp used in making the packing material to put between bottles or glass cans is a poorly cooked batch of fir waste products—often a whole batch of this material will be shipped with some still untreated fibers. Then these packers at the glass factory—frequently preceded by the men who unloaded the carload of pulp-paper—would begin to show up with typical fir-poisoned eyes. For two years, I was able to “date” a shipment of this kind.

As to the case to be reported: On November 15, 1941, Mrs. V. H., aged about 28 years, came to my office with the following history. In August she had a paper-dust condition in the right eye

which was treated by a local physician. The eye had never become well. She had worked at intervals until the 19th of October, when she had to stop. Treatment by removal of dust and other measures seemed temporary, and she finally was sent to a specialist (fig. 2). He reported her trouble to be purely a condition of the eye and not compensable. She disagreed, went to another office and was told all previous treatments were wrong, as well as the diagnosis. Her condition still did not improve. It was then that she was sent to me, some 90 days after the accident. Her complaint at that time was that the eye was in an awful shape—“draws and burns and hurts *all* the time; waters almost continuously.” Use of the eye caused much redness; headache was rather constant, worse around the right eye, requiring many resting tablets.

Examination of the right eye at this time showed very red external margins, the bulbar conjunctiva to be injected. The anterior surface of the cornea was hazy and Bowman's membrane rough, below, at the 5:30-o'clock position. The iris

Fig. 3 (Ruby). Later development in the author's case, prior to enucleation.

seemed fixed and atrophied in several places. Tension was increased to fingers. Glasses obtained some months previous to incurrence of the disability gave no help.

The fundus showed little change and could be viewed through the distorted pupil as well as through two of the atrophic spots in the iris. During the next six weeks, repeated examinations showed variations in the haziness of the cornea, which, at times, would wrinkle ahead of the closing lids. Pontocaine ointment would give temporary relief to the symptoms. The vision and the headache were somewhat erratic. The tension was not improved.

In February, or 90 days after the patient had come under my observation, she went to Indianapolis for a visit and was referred to Dr. Masters for observation and treatment. She returned to me later in the spring with the condition unimproved. In June, the compensation question came to a head, for she had not worked since the previous October 19th. In the meantime, the colobomata in the iris continued to extend and enlarge so that a light held under the lower lid would give a beautiful picture of iris atrophy (fig. 3).

In August—settlement having been made out of court, in June, on the basis of 20 percent loss of vision—the patient decided to give up the eye, and it was enucleated on August 11, 1942 (fig. 4). Recovery was uneventful. The left eye has had absolutely no symptoms during the progress of the case.

PATHOLOGIC REPORT, as received from the Army Medical Museum.

Gross: The specimen consists of a partly collapsed eye measuring 24 by 25.5 by 23.5 mm. There are irregular thickening and opacity of the cornea and multiple colobomata of the iris. The eye is opened in the horizontal plane. The sclera is thin, the lens opaque, and the vitreous cloudy. The optic nerve is too short for cross section.

Microscopic: There is epidermalization of the corneal epithelium over a dense

pannus. Bowman's membrane is rather thick and prominent and, immediately beneath it, there is scarring of the corneal lamellae. Descemet's membrane is thick peripherally. A peripheral anterior synchia obliterates the filtration angle. There is some cystoid degeneration of the pigment epithelium of the iris and of the

Fig. 4 (Ruby). Section of enucleated eye.

anterior ciliary body. On the temporal side, in the sections examined, only the anteriorly adherent peripheral portion of the iris remains, with pigment epithelium piled up on its posterior surface. On the nasal side there is a wide coloboma of the iris, and the pupillary portion shows ectropion uveae, vascularization behind the sphincter muscle, and loss of stroma in front of it. On this the stroma appears frayed at the margins of the coloboma. The lens does not appear to be desquamated. There is little hyalinization of the ciliary processes. The choroid is not remarkable. There are cystic degeneration of the retina at the ora serrata and slight edema of the outer plexiform layer at the macula, but otherwise significant changes are not seen in this coat. The lamina cribrosa is depressed.

Diaognoses: Essential atrophy of the

iris; glaucoma, secondary: pannus degenerativus.

COMMENT

There are some 35 reports of cases of essential atrophy of the iris in the recent American literature. The condition is most often found in young adults, although others may have it. This may depend on the rapidity of its development. It is not a congenital condition, but progressive. Nor is it infectious, for in only one or two cases has it ever affected the second eye, and even these cases were not proved. The first authentic sign is a displacement of the pupil toward one side. This seems to result rather from atrophy on the opposite side than from excessive stimulation on the near side.

The cause of the atrophy has been much discussed. Some authorities considered glaucoma to be the cause, but the case of Barr and Fralick showed only a "24 point" reading on the Schiötz tonometer. The other theory points to a persistence of some of the embryonic activity in the eye—the process by which the hyaloid artery is destroyed, and the membrane dissolved in the pupillary area. Later in life, from some unknown cause, this process is reactivated, the atrophy, according to Casey Wood, seeming to start on the anterior surface of the iris, as the uveal layer often folds out over the edge of the coloboma. In a recent report glaucoma was considered to be the result of the atrophy. In the pathologic report of the eye, here described, there were adhesions from the base of the iris to the cornea, as well as some deposits of iris material about the periphery, shutting off the natural drainage from the eye. Other cases, however, showed no inflammatory condition, nor increase in white cells about any of the tissues. The final conclusions have been variously described as follows: de Schweinitz calls the condition an "abiotrophy or premature senility

with death of cells." Kricker calls it "a combination of embryogenic, cytolytic process of late development."

As to treatment of the case: Nothing except analgesics, local or general, seemed of the slightest value. When the eye was admittedly doomed, the greatest comfort was received by the local application of pontocaine and atropine. The latter was used upon the assumption that the "absolute-glaucoma" eye is painless, and this proved true in the eye, herein reported. The distress from light was relieved by a shield over the patient's glasses. Her vision dropped to 7/200 before enucleation. Following enucleation the refraction of the good eye was practically as it had been for two years. McKeown, in discussing treatment, states that whereas absolute glaucoma causes the blindness, it is secondary and not inflammatory; for the second eye practically always escapes.

As to the "paper dust" condition: The pathologic report showed that the cornea had been injured, at least once, maybe oftener. The "looseness" of Bowman's membrane—almost herpetiform in character—made the cornea more susceptible to the spicules of fir. The pannus could easily result from the repeated severe irritation.

CONCLUSIONS

1. The patient had "paper-dust" irritation.
2. She also had an underlying and previous essential atrophy of the iris.
3. The second condition made her suffering worse, and the duration longer.
4. While she would have suffered some, and would have lost the eye at approximately the same time, because of the atrophy, the reaction of the eye to the paper-dust irritation may have accelerated the other changes.

THE GEOGRAPHICAL DISTRIBUTION OF OCULAR INFECTIONS*

WITH SPECIAL REFERENCE TO TROPICAL AND SUBTROPICAL COUNTRIES

CHARLES WEISS, M.D.

San Francisco

Experience has shown that it is important to become familiar with the distribution of infectious diseases in the active combat zones of the war. While McKinley's work on "A geography of disease"¹ and Mumford and Moore's "Preliminary report on parasitic and other infectious diseases of the Japanese mandated islands and Guam"² cover the subject of transmissible diseases in general, they contain very little information on infections of the eye. As observed by Lindner³ and others during the first World War, epidemic and endemic dis-

eases of the eye may produce a high non-effective rate among armed forces.

Conjunctival infections are very common in tropical and subtropical countries "because of the presence of excessive heat, dust, and sunlight; crowding, filth, and lack of water; malnutrition and vitamin deficiencies. To these factors may be added the enormous number of flies and other insects, and the superstitious customs prevalent among the indigenous population."⁴

In table 1 the most important infectious diseases of the eye are arranged according to broad geographical zones, since it was impossible to obtain more specific information from the literature.⁵⁻¹⁰

TABLE 1
GEOGRAPHICAL DISTRIBUTION OF OCULAR INFECTIONS

1. NORTH AFRICA (TUNIS, ALGERIA, EGYPT, ABYSSINIA, AND MOROCCO) AND WEST AFRICA

Virus diseases: trachoma, punctate keratitis, yellow fever (produces subconjunctival hemorrhages—West Africa); smallpox (blindness).

Bacterial diseases: acute conjunctivitis due to *Pneumococcus* or Koch-Weeks bacillus ("pink-eye"); frambesia tropica (yaws); recurrent fever (iritis, iridocyclitis, choroiditis); syphilitic keratitis; gonorrheal ophthalmia; angular conjunctivitis due to *Morax* bacillus; leprosy; *M. tuberculosis*; plague (corneal ulcers, iritis, iridocyclitis); gonorrheal ophthalmia.

Parasitic infestations: *D. latum* (*Sparganum mansonii*); filariasis (*F. loa-loa*—West Africa); trypanosomiasis (causes keratitis, purulent conjunctivitis, iritis, iridocyclitis, inflammation of eyelids).

Flies and Insects (Myiasis): Ant stings; worm similar to screw worm.

2. MADAGASCAR

Virus diseases: trachoma.

Bacterial diseases: syphilitic keratitis; "ulcus serpens" (*Pneumococcus*); leprosy; tuberculosis.

Fungus diseases: aspergillosis (corneal ulcer).

Miscellaneous: phlyctenular kerato-conjunctivitis.

3. CHINA, INDIA, AND INDO-CHINA

Virus diseases: trachoma; Samoan (inclusion) conjunctivitis; epidemic punctate keratitis (Ceylon, Madras, Bengal); smallpox (Madras, Ceylon, Cochin).

Bacterial diseases: acute conjunctivitis ("pink-eye"—Cochin, Bombay, Madras); gonorrheal ophthalmia (adults); conjunctivitis due to *Morax* bacillus; conjunctivitis due to *Staphylococcus*, *Pneumococcus*; blennorrhoea neonatorum (*Gonococcus*); recurrent fever (iritis, iridocyclitis, choroiditis); plague (corneal ulcers, iritis, iridocyclitis—Madras, Ceylon, Cochin); syphilitic keratitis (Hanoi); "ulcus serpens" (*Pneumococcus*); leprosy; tuberculosis; frambesia tropica (yaws—Ceylon).

Fungus diseases: Polyps on conjunctiva due to *Rhinosporidium seeberi* (Madras, Ceylon, Cochin); *Rhinosporidium kincalpi* on lid (Madras, Ceylon, Cochin).

Parasitic infestations: *D. latum* (*Sparganum mansonii*—China, Annam, Tonkin); filariasis (China, Annam); blinding filariasis (Bombay, Madras); Kala-azar (*L. donovani*—Central China, Peiping); *T. solium* (cysticercus—China); *echinococcus granulosus* of orbit (China).

4. DUTCH EAST INDIES AND MALAYA

Virus diseases: trachoma; punctate keratitis; smallpox.

Bacterial diseases: acute conjunctivitis ("pink-eye"); conjunctivitis due to *Staphylococcus*, *Pneumococcus* (Java); conjunctivitis (*Morax* bacillus—Kuala-Lumpur); diphtheritic conjunctivitis; blennorrhoea (*Gonococcus*) in adults; blennorrhoea neonatorum (*Gonococcus*); serpiginous ulcer (*Pneumococcus*); tuberculous iritis; frambesia tropica (yaws); plague (Singapore); syphilitic keratitis; leprosy.

Fungus diseases: conjunctivitis due to yeasts (Java).

Parasitic infestations: *Filaria bancrofti* (elephantiasis of eyelids—Sumatra); leeches in conjunctiva.

Flies and Insects (Myiasis): Buffalo louse in conjunctiva.

5. SOUTH PACIFIC ISLANDS (INCLUDING SAMOA AND HAWAII)

Virus diseases: Samoan (inclusion) conjunctivitis (Tonga, Fiji group, Savaii, Manua, Samoan archipelago); vaccinia infections of lids; epidemic keratoconjunctivitis (Hawaii).

Bacterial diseases: Frambesia tropica (yaws) Ellice and Tokelau Islands; conjunctivitis due to *Morax* bacillus (British East Indies); tuberculosis (Ellice and Tokelau Islands); leprosy; syphilis; catarrhal conjunctivitis with corneal ulcer (Ellice Islands).

Fungus diseases: conjunctivitis due to yeasts.

Parasitic infestations: filariasis of eyelids (Ellice and Tokelau Islands).

6. JAPAN AND MANDATED ISLANDS

Virus diseases: trachoma; lymphogranuloma venereum; inclusion conjunctivitis (Saipan).

Bacterial diseases: oculo-glandular tularemia; leprosy; tuberculosis.

Fungus diseases: *Aspergillus fumigatus* (kerato-mycosis).

Parasitic infestations: *D. latum* (*Sparganum mansonii*) in conjunctiva and eyelids; leeches in conjunctiva.

Flies and Insects (Myiasis): akamushi tick (carrier of tsutsugamushi virus) may bite eyelids.

7. AUSTRALIA, NEW ZEALAND, AND TASMANIA

Virus diseases: epidemic keratoconjunctivitis; Samoan (inclusion) conjunctivitis; trachoma.

Bacterial diseases: leprosy; tuberculosis.

Parasitic infestations: *D. latum* (*Sparganum mansonii*) causes tumor of eyelids.

8. PALESTINE, SYRIA, AND TURKEY

Virus diseases: trachoma; pappataci fever.

Bacterial diseases: acute conjunctivitis ("pink-eye") due to *Pneumococcus* and Koch-Weeks bacillus, conjunctivitis and keratitis due to the *Morax* bacillus; gonorrheal blennorrhea; leprosy; tuberculosis.

Parasitic infestations: leishmaniasis; malaria.

Flies and Insects (Myiases): sand flies.

9. MEXICO, CENTRAL AMERICA, AND CARIBBEAN ISLANDS

Virus diseases: trachoma; yellow fever (subconjunctival hemorrhage); typhus fever.

Bacterial diseases: "pink-eye," acute conjunctivitis due to Koch-Weeks bacillus (Colombia); recurrent fever (iritis, iridocyclitis, choroiditis); frambesia tropica (yaws—West Indies, Cuba); leprosy; tuberculosis.

Parasitic infestations: filariasis ("blinding filaria"—Guatemala, Mexico, Cuba).

Flies and Insects (Myiases): flies (Costa Rica, Colombia, Puerto Rico, Mexico); ant stings (Puerto Rico).

10. SOUTH AMERICA

Virus diseases: trachoma; yellow fever (causes subconjunctival hemorrhage—Brazil).

Bacterial diseases: frambesia tropica (yaws); plague (corneal ulcer, iritis, iridocyclitis—Brazil); leprosy; tuberculosis; "pink-eye" (Koch-Weeks bacillus—Brazil).

Fungus diseases: *Rhinosporidium seeberi* (conjunctival cysts); actinomyces. *Aspergillus niger* causes "saporanga" in Brazil.

Parasitic infestations: Leishmanian keratitis (Brazil); edema of lids from *Trypanosoma cruzi* (Brazil); *echinococcus granulosus* (Brazil, Argentina); *T. solium* (cysticercus—Argentina, Brazil); *D. latum* (*Sparganum mansonii*—British Guiana).

Flies and Insects (Myiases): Screw worms (gold bottle fly—French Guiana).

NOTES, CASES, INSTRUMENTS

THE USE OF NAPHTHOCAINE AS A LOCAL ANESTHETIC IN OPHTHALMOLOGY

ROY ALLEN STEWART, M.D.*

Baltimore

Naphthocaine^{1, 2} is the mono-hydrochloride of beta-diethylaminoethyl ester of 4-amino-1-naphthoic acid. Its structural formula is as follows:

It is a yellowish crystalline material soluble up to 2 percent in distilled water, making a clear pale-yellow solution with a pH of about 4.4. The solutions used for this clinical study contained sodium bisulfite, chlorotone, and adrenalin 1:50,000; the naphthocaine† was 0.2-percent, 0.3-percent, and 1.0-percent. The 0.3-percent and 1.0-percent solutions were superior in their anesthetic properties to the 0.2-percent solution, but even the 0.2-percent solution was superior to pro-

caine. I could not discern any difference in the anesthetic properties between 0.3-percent naphthocaine and 1.0-percent naphthocaine.

When 4-percent cocaine instillations and 5.0 c.c. of 2-percent procaine injections are used as a local anesthetic in intraocular surgery there appear to be definite disadvantages. When the superior-rectus suture is placed the patient usually has a definite pain. Likewise there is pain when an iridectomy is performed. Akinesia is often faulty. Postoperatively, the patient often has pain in the eye that has been operated on within a few hours or less time.

When 4-percent cocaine instillations and 5.0 c.c. of 0.3-percent naphthocaine injections are used in intraocular surgery there is usually no pain when the superior-rectus suture is placed, and no pain when an iridectomy is done. Akinesia is really excellent. The average length of time before postoperative pain begins is 8 to 10 hours.

At the Baltimore Eye, Ear, and Throat Hospital we have made a clinical study of naphthocaine as a local anesthetic in ophthalmology. The following list of operations under this anesthetic have been performed:

* From the Baltimore Eye, Ear, and Throat Hospital.

† The naphthocaine was supplied by courtesy of Parke, Davis, and Co.

	Number of Cases	Amount Injected	Instillations
		c.c.	
Intracapsular cataract extraction	20	5.0	4% cocaine
Iridectomy	1	5.0	4% cocaine
Iridencleisis	3	5.0	4% cocaine
Lagrange anterior sclerectomy	1	5.0	4% cocaine
Posterior sclerotomy	1	1.0	4% cocaine
Walker operation for retinal detachment	2	8.0	4% cocaine
Enucleation	1	8.0	4% cocaine
Suture of lacerated lids	1	5.0	4% cocaine
Lacrimal probing	5	1.0	4% cocaine
Reese resection and Jameson recession	1	5.0	4% cocaine
Curretment of chalazia	15	0.5	0.5% pontocaine
Conjunctival plastic for symblepharon	1	2.0	0.5% pontocaine
Kuhnt-Szymanowski operation for ectropion	1	13.0	0.5% pontocaine

The striking features of local anesthesia with naphthocaine are its immediate anesthetic effect after injection, the excellent akinesia, the real anesthesia during the operation, and the long duration of the anesthesia. The Walker operation is a real test of a local anesthetic. In the two cases reported the patients complained of no pain during the operation and required only codeine 0.5 gr. and 10 gr. of acetylsalicylic acid 10 hours postoperatively. When this procedure was carried out with procaine the patient was rather uncomfortable and the postoperative pain somewhat severe.

Although naphthocaine works best when injected it has a good anesthetic effect upon instillation, and corneal foreign

bodies can be removed, tonometry and other minor procedures can be effected without pain to the patient. When naphthocaine is injected into the lacrimal sac by way of the canaliculus, lacrimal probing can be done with very little discomfort to the patient. In the cases reported no patient developed toxic symptoms,³⁻⁵ nor any appreciable change in pulse, respiration, or blood pressure. The Nose and Throat Department has used 30.0 c.c. of naphthocaine for injection many times and there has been no reaction to the drug.

From this small experience with naphthocaine it would seem to be the best drug for obtaining local anesthesia in ophthalmology.

NOMINAL DUCTION AND TRUE DUCTION POWER

JOSEPH I. PASCAL, M.D.
New York

One of the striking points in Abraham's article on "Near horizontal phoria and duction tests" in the March, 1943, issue of the *American Journal of Ophthalmology* is the wide discrepancy in the adduction-abduction ratio at near in the normal group as found by him and as found by Berens *et al.* in their investigation. The latter found a ratio of practically 2:1 of adduction to abduction, while Abraham found a ratio of practically 1:1. However, these results may not be so far apart as

they seem if we take into consideration the difference between nominal ductions and true ductions. Nominal ductions refer to the amount of prism power, base out or base in, overcome without reference to an existing phoria; true ductions refer to the amount of prism power, base out or base in, overcome but with reference to an existing phoria. True duction power measures what has been called breadth of fusion and refers to a forced movement of the eyes inward or outward in order to maintain or regain single binocular vision.

To take case 1, table 1, as an instance. This patient had 6 delta of exophoria (I prefer the short term delta to the clumsy term prism-diopter). The nominal abduc-

tion was 20 delta. But the first 6-delta prism, base in, did not induce a *forced* movement outward in order to maintain fusion. It permitted a relaxation of 6 delta to the position of equilibrium. Beyond the 6 delta the base-in prism produced a forced outward rotation in order to maintain fusion. This amounts to 14 delta, which represents the true abduction.

The nominal adduction in this case was 19 delta. But the patient began the test with a forced inward rotation, a true adduction of 6 delta, to compensate for his 6 delta of exophoria. Therefore the total

true adduction was 25 delta. The ratio of adduction to abduction is as 25:14, nearly 2:1. If the amount of exophoria is added to the adduction and subtracted from the abduction, the ratio in most of the cases will be nearly 2:1. The fact that Berens's findings were made at a closer range, at 25 cm. to Abraham's 33 cm., may account for the somewhat greater relative adduction in the former set. At the closer point, the sense of nearness may be more effective in inducing the convergence activity.

37 West Ninety-seventh Street.

SOCIETY PROCEEDINGS

EDITED BY DR. DONALD J. LYLE

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

October 5, 1942

DR. ISADORE GIVNER, *presiding*

STANDARDIZATION OF THE SCHIÖTZ TONOMETER

DR. ADOLPH POSNER presented an exhibit and demonstration on this subject during the instructional hour.

DISASSOCIATION OF THYROTOXICOSIS AND OPHTHALMOPATHY IN GRAVES'S DIS- EASE

DR. SAUL HERTZ stated that there are cases in which no correlation between the degree of ophthalmopathy and the degree of thyrotoxicosis in Graves's disease exists. Low degrees of thyrotoxicosis may exist with serious ophthalmopathy, and vice versa. Cases of serious eye disturbances require special handling both from the diagnostic and therapeutic point of view and must be considered apart from the ordinary cases of Graves's disease. The eye disturbances often improve with iodine therapy, but the best results

have been obtained with iodine and thyroid. Occasionally it has been necessary to add X-ray treatment to the thyroid. Thyroidectomy is definitely contraindicated in this type of case.

A recent survey by Dr. J. H. Means has indicated that, in a group of representative clinics, thyroidectomy preceded the orbital decompressions in over 90 percent of cases requiring orbital decompression. On the other hand, no orbital decompressions have been performed at the Massachusetts General Hospital Clinic for three years since the institution of the present policy of averting thyroidectomy in cases suspected of being in the special group of ophthalmopathic Graves's disease.

Pictures were shown to illustrate the difference between cases of the ordinary type of Graves's disease and those of the progressive or malignant exophthalmic type.

Discussion. Dr. Maurice Bruger stated that Dr. Givner and he had studied the effect of vitamins B₆ and E in eight patients with postthyroidectomy exoph-

thalmos. These vitamins were chosen because of their recognized value in some forms of muscular dystrophy. It was thought that there might be some influence on the myopathic changes in the extraocular muscles, the prime factor in the causation of exophthalmos. In addition, three patients were given ergotamine tartrate and one prostigmine bromide. Vitamins B₆ and E were without effect on the degree of exophthalmos or on the extent of the lid retraction. Ergotamine tartrate, however, improved the Dalrymple sign appreciably without altering the exophthalmos. Prostigmine bromide was without measurable effect.

Dr. Daniel Kravitz asked Dr. Hertz how he accounted for the exophthalmos when the ocular muscles were not enlarged.

Dr. H. M. Katzin asked Dr. Hertz to enlarge on the subject of treatment of malignant exophthalmos with X-ray therapy to the thyroid gland.

Dr. Hertz, in closing, said that from the medical point of view, it seems not unbelievable that one could have edema of the orbital tissues and that the muscles need not necessarily be involved. He cautioned that one has to be very strict in placing the patient in the category of malignant exophthalmos. His experience with X-ray treatment has been limited. It has been effective in a few cases in which iodine and thyroid therapy did not fully control the condition.

SURGICAL PROCEDURES FOR EXOPHTHALMOS IN HYPERTHYROIDISM

DR. EDMUND B. SPAETH stated that the surgical treatment of exophthalmos from thyrotoxicosis depends upon the degree of exophthalmos present, the rapidity of its progress, and the period at which it appears as a surgical situation, such as the stationary exophthalmos of thyrotoxicosis (regardless of whether or not a thyroidec-

tomy has been done), and that type of exophthalmos which follows after a thyroidectomy.

Other complications, such as oculomotor disturbances, retraction of the upper lid, conjunctival edema, and an endangered cornea from lagophthalmos are all additional factors, frequently of serious import. It is these complications, as they appear, that control the seriousness of the condition being treated; also they decide, to a very large extent, the type of surgery that is necessary in any given case.

Malignant or progressive exophthalmos can be treated successfully only by some type of orbital decompression. The subzygomatic route for this, it seems, is as satisfactory a procedure as is the transfrontal approach for the removal of the roof of the orbit. Anatomically there should be no choice between the two when considering this type of exophthalmos.

Discussion. Dr. John H. Dunnington stated that operations done for cosmetic reasons are often disappointing to the patient. They expect too much in spite of our efforts to depict the true picture to them. He has, therefore, been inclined to operate only when the lagophthalmos or other symptoms demand action. Recession of the levator as described by Goldstein will remove the disfigurement caused by retraction of the upper lid, and in his opinion its use should be restricted to cases manifesting a marked exposure of the sclera above the upper corneoscleral margin. Lateral tarsorrhaphy narrows the palpebral fissure satisfactorily, and he believes the best technique is that described by Wheeler. In this operation a tongue of tarsus denuded of its epithelium is inserted into the opposite lid. This operation gives an acute angle to the external canthus and is far superior to the rounded one that follows after the use of the Fuchs technique.

The selection of the lid from which the tongue is to be carved will depend upon whether one wishes primarily to lower the upper lid or to raise the lower lid. A tongue from the upper lid inserted into the lower lid narrows the fissure chiefly by lowering the upper lid, while the reverse is true when the tongue is taken from the lower lid and inserted into the upper lid.

Intermarginal adhesions afford the necessary protection for the cornea in cases of lagophthalmic keratitis and should be inserted prior to the onset of extensive chemosis of the conjunctiva and edema of the lids. In his experience retrobulbar drainage for a prolapsed chemotic conjunctiva has not been necessary. Gentle massage with a glass spatula combined with liberal use of an antiseptic ointment has proved sufficient in the majority of instances.

ORBITAL DECOMPRESSION FOR PROGRESSIVE EXOPHTHALMOS IN THYROID DISEASE

DR. JAMES L. POPPEN recounted surgical experiences in relation to orbital decompression for progressive exophthalmos in a series of 25 consecutive cases at the Lahey Clinic. He stated that there is an optimum time for the operation and that it should not be withheld until the development of chemosis and perhaps corneal ulceration. Indications for the procedure consist of progressive exophthalmos of high grade together with progressive visual symptoms and often changes in the optic-nerve head. The operation is not serious and, in his experience, there is no operative mortality. The technique of the Naffziger operation with slight modifications was described.

Procrastination is to be deprecated when visual loss is detected, inasmuch as all other palliative treatment has been of no effect. The only possible exception seems to be the preoperative determina-

tion of the basal metabolic rate, in order to determine whether Lugol's solution and possible excision of thyroid remnants should be considered.

The symptom of diplopia in relation to extraocular palsies should receive attention. While such a condition may persist to some degree or possibly result from the operation, it is usually amenable to minor operative treatment in those cases that do not clear up spontaneously. Following the operation there is immediate postoperative improvement in the exophthalmos and a gradual recession usually continues over a period of years.

Discussion. Dr. Howard Naffziger described the characteristic pathologic changes found in the ocular muscles in malignant exophthalmos. He emphasized the points that the condition of the muscles in the ordinary cases of exophthalmic goiter is not known and that muscle changes are not necessarily the same in cases of malignant exophthalmos. He described his technique of orbital decompression and stated that a broader exposure can be obtained than with the subzygomatic approach. One reason for confusion as to the presence or absence of exophthalmos has been failure to distinguish "stare," or retraction of the upper or lower lid, from protrusion of the eyeball. Exophthalmos can be confirmed only by careful measurement with the Hertel exophthalmometer. Unilateral exophthalmos speaks for orbital neoplasm, rather than thyroid disease. Soley has found that eyes of more than 50 percent of patients with toxic diffuse goiter became measurably more prominent after thyroidectomy, contrary to the clinical impression of most clinicians.

Dr. Martin Cohen stated that he regarded the Naffziger operation formidable and that he has obtained the same results with the Krönlein operation.

COLORADO OPHTHALMOLOG-
ICAL SOCIETY

October 24, 1942

DR. GUY HOPKINS, *presiding*TREATMENT OF CATARACT WITH LYM-
PHOGOGUESDR. EDWARD R. NEEPER presented
L. M., a woman, aged 42 years, who was
first seen in February, 1937. She gave a
history of failing vision in the right eye
for the past 15 months. She also com-
plained of having had eczema all her life
and showed definite signs of allergy. The
vision at that time was R.E. 20/200; L.E.
20/20-4. Vision was unimproved with
lenses. The right lens was cataractous
throughout. The left lens had a posterior
polar cataract about 2 mm. in diameter.
Lymphogogues have been used once eachweek since that time. On July 8, 1942,
examination showed that the right eye
had a mature cataract, but the left lens
had remained stationary.DR. NEEPER also presented the case of
C. M. who had been under observation
for a period of over 25 years. In 1933 she
showed beginning cataracts, more marked
in the left eye. Lymphogogues were
started in November, 1934, and used
once each week since that time. At this
time vision, with correction, was normal.REMNANTS OF THROMBOSIS OF CENTRAL
RETINAL VEIN, RIGHT EYEDR. FRITZ NELSON said that J. J. S.,
a man aged 53 years, complained of sud-
den loss of vision, right eye, two years
ago. There was, however, partial return
of vision. The left eye had always been
normal. Examination showed remnants
of a thrombosis of the central retinal
vein, right eye, with the formation of
a large number of collateral vessels on
the surface of the disc. The patient had
had difficulty in swallowing, especially
cold foods, for many years.X-ray examination showed a large
diverticulum of the esophagus. It was
suggested that there is a causal connec-
tion between thrombosis of the central
retinal vein and the diverticulum, owing
to compression. On the other hand fre-
quent exposure to carbon monoxide may
be a contributing factor in the cause of
thrombosis.

TUMOR OF OPTIC NERVE

DR. FRITZ NELSON presented R. C. E.,
a woman, aged 43 years, who was first
seen in April, 1942, with a brown, tumor-
like mass, semispherical in shape, cover-
ing the upper nasal third of the disc in
the right eye and extending into the
adjacent area. There was suspicion of a
slowly growing malignant melanoma. No
treatment was advised for the present,
but close observation was recommended.

CONTACT LENSES

DR. FRITZ NELSON said that C. A. J., a man, aged 47 years, had a pronounced keratoconus in both eyes. He was fitted with aspheric contact lenses in June, 1941, and since that time has been able to continue his occupation as a sheet-metal worker very satisfactorily.

CATARACT EXTRACTION WITH COMPLICATIONS

DR. FRITZ NELSON presented L. S. S., a man, aged 58 years, who had had a cataract extraction, right eye, in August, 1940, with uneventful recovery. The left eye was operated on without iridectomy on August 4, 1942; there were no complications. He was released from the hospital August 12, 1942. An iritis developed on August 15th, followed by secondary glaucoma, which did not respond to treatment. On August 31st there was beginning panophthalmitis, with exophthalmos and chemosis. An Elliot trephining was performed on August 31st. A culture of the chamber fluid showed pure *Staphylococcus aureus*. Immediate medication was instituted, with sulfathiazole grams 4 as an initial dose, and grams 1.5 every four hours. There was complete recovery within three weeks.

NEW GROWTH

DR. VON H. BROBECK said that L. B. C., a man, aged 61 years, gave a history of redness and new growth on the right eye of three years' duration. During this past summer there was some pain in the eye and blurring of vision. Examination revealed an irregular triangular growth on the temporal episclera which invaded the cornea over its outer third, with vascularization. Biopsy report showed an incipient basal-cell carcinoma.

Discussion. Dr. E. M. Marbourg remarked that clinically it resembled pemphigus.

ISOLATED PARESIS OF THE SUPERIOR OBLIQUE

DR. GEORGE H. STINE and DR. K. H. CHAPMAN presented J. A. W., a man, aged 57 years, seen for the first time in September, 1942, with a history of having fallen from a ladder and striking the back of his head and shoulders. Diplopia was noticed immediately after the accident. External examination of the eyes was negative, except for left hyperphoria, with the deviation greatest on looking down and to the right, the left eye lagging slightly. There was a slight increase in the deviation when fixating with the left eye. Measurement of the deviation with the Lancaster red-green test showed about three arc degrees of vertical deviation in the primary position, with the deviation greatest in the lower right field, the left image also being tilted down and to the left. The fundus was normal in each eye. Examination revealed no other physical injuries. The patient was placed on potassium iodide, 10 drops, three times a day, and the left eye was occluded to avoid diplopia. In three months the patient complained of practically no double vision except when his head was tilted far backward. The vision was 1.3 in each eye.

Dr. Stine and Dr. Chapman reported another case, a man, aged 48 years, with a bilateral fourth-nerve paresis, following a kick in the head by a horse. The condition cleared up in four months' time.

The third case was that of a man, aged 51 years, who also fell from a ladder. He showed a slight paresis of the left superior oblique which was much improved in one month's time.

The fourth case was observed in a woman, aged 63 years, who developed diplopia suddenly one day. She showed symptoms of hypertension and arteriosclerosis. Examination of the ocular rotations and diplopia fields indicated paresis

of the right superior oblique, the diplopia increasing when the head was tilted to the right, whereas single vision was obtained on tilting the head to the left. There was considerable improvement in the diplopia in one month's time under potassium-iodide medication.

Dr. Stine pointed out the value of the head-tilting test after the method of Bielschowsky, which when positive was pathognomonic of superior-oblique involvement. This test could be done with the hand stereoscope held tightly to the face and rotated with it, using a horizontal line on a test card, half of which was green and the other half red, to identify it with the right and left eye, respectively.

GLAUCOMA AND UVEITIS

DR. GEORGE H. STINE said that J. P., a woman, aged 50 years, who had been under his care since December, 1941, complained of blurred vision of the left eye which had definitely become worse the past two weeks, accompanied by some deep pain. The vision of the right eye was also blurred. She had had some badly infected teeth extracted two weeks previously and had also been treated for a mild sinusitis.

The right eye showed a low-grade uveitis with a few gray keratitic precipitates, a few pigment deposits in the pupillary margin, a few cells in the aqueous, and some fine dustlike opacities in the vitreous. The fundus was otherwise negative.

The left eye was in a state of advanced simple glaucoma. There was no evidence of a uveitic process, now nor previously, in this eye. There was some glaucomatous atrophy and cupping of the disc.

The tension of the right eye had never been found to be above 26 mm. Hg (new Schiötz). The tension of the left eye was 65 mm. Hg (Schiötz) but was reduced to 23 mm. Hg by the use of pilocarpine and eserine. However, this reduction was not

maintained. The field of vision in the left eye showed a severe concentric contraction. The right visual field was normal. Iridencleisis was done on the left eye in December, 1941, with an excellent result, although the vision was not improved beyond the ability to detect hand movements at one meter. The vision of the right eye when first seen was 0.9 but was now reduced to 0.4. The general physical examination, including tests for syphilis and undulant fever, revealed no pathologic changes. The intradermal tuberculin test was positive to 0.005 mg. tuberculin. The patient has been under treatment with increasing doses of tuberculin; instillations of dionin and atropine; several intravenous injections of typhoid H antigen, dosage up to 60 million; Pregl's iodine packs; and Reese paracentesis, which have controlled the condition but little to date. Mild X-ray therapy to the eye was being instituted.

Walter A. Ohmart,
Secretary.

ASTIGMATIC DETERMINATIONS—A CLINICAL COMPARISON OF METHODS

DR. JULIAN GINSBERG gave a summary of the astigmatic tests commonly used by ophthalmologists, with the conclusion that there is no universal astigmatic test for all problems in refraction and therefore all methods should be understood and combined for the best results.

MODIFIED PTOSIS OPERATION (with films)

DR. ORWYN ELLIS presented a procedure for the correction of ptosis based on the Motais's operation which was published in the proceedings of the

Pacific Coast Oto-Ophthalmological Society, 1942; also in this Journal (1943, October).

CYCLODIATHERMY IN GLAUCOMA

DR. CLARENCE H. ALBAUGH said that until recently successful glaucoma surgery was based on the conception of increasing the adequacy of aqueous escape. Furthermore, there was no advance of a major proportion in the type of surgery done in the past decade. Our obscure knowledge of the basic cause of glaucoma was to a great extent responsible for this situation. Also, it was as yet impossible to produce typical chronic simple glaucoma in laboratory animals and thus much of the surgical experimental work was limited to the human being. The idea of cutting down the amount of aqueous formed was by no means a new one; however, the means of doing such a thing safely was not in current use until relatively recently. Since the diathermy had become available and had been tested on the eye in procedures for separated retina, use could now be made of it in cases of glaucoma also. It should be emphasized at the outset that cyclodiathermy is not a panacea for glaucoma and should be used only in those cases in which other time-tested methods of treatment had failed. Perhaps the first use of the idea of cutting down the amount of aqueous formed was the cyclo-dialysis of Heine in 1905. Shahan and Post, in 1921, in this country attacked the ciliary body with the thermophore

and, in 1924, Verhoeff actually cut out a portion of the ciliary body. In 1940, Vogt reported the first destruction of the ciliary body with diathermy.

Drs. Dunphy and Albaugh used the following procedure: (1) Perforating cyclodiathermy; in this operation Walker points were introduced in two rows at 3 mm. and 5 mm. from the limbus over half of the globe. (2) Nonperforating; here a Weve flat electrode is applied in the same area but no perforations are made. We used atropine postoperatively. The complications were few and not serious. The operation was simple and did not appear to disturb the eye.

The advantages were that there was no collapse of the anterior chamber; iris and cornea were not disturbed; the patient was able to resume normal activity within 24 hours, and the danger of sympathetic ophthalmia was much less than in the usual surgery. Indications for the operation were: hemorrhagic glaucoma, aphakia with glaucoma, buphthalmos, occasionally primary glaucoma, and, depending upon the particular case, it could be assumed that about 60 percent of the cases would be successfully controlled; in another 10 to 15 percent the tension might remain elevated but the patient would be comfortable.

It was to be hoped that, although this was not a "cure-all" procedure, other new developments may be made along the same lines.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, HARRY S. GRADLE, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review and reports of society proceedings to *Dr. Lawrence T. Post, 640 South Kingshighway, Saint Louis 10, Missouri*. Manuscripts should be typed in double space, with wide margins.

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver, Colorado*.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

REHABILITATION OF THE WAR-BLINDED

Elsewhere in this issue Sir Ian Frazier's "Whereas I was blind" is reviewed. The account of his own experience and the founding and development of St. Dunstan's in the past 25 years may well serve as examples of what may be accomplished for our own war-blinded in this country.

At one time it appeared the Veterans Administration would be the organization in the United States that would take over the care of the war-blinded immediately upon release from the base hospital where care of the acute condition is to be completed. Now, however, a some-

what different plan is contemplated. It is understandable that an organization that will have to concern itself with ten million and more men cannot devote much time to the social rehabilitation of perhaps a thousand men, and will be content to see that the financial help provided by the nation is administered properly to this blinded group. For perhaps 20 percent of these this will be the only help that they desire, but an effort to provide cultural, social, and instructive aid to any who desire it and are capable of utilizing it must be made.

The latest plan for our men involves admission to one of two hospitals, one on the Atlantic and the other on the Pacific

coast, especially designated for medical and surgical care of those with eye injuries or eye diseases. As soon as possible they will be discharged to an eye rehabilitation center under Army direction where both Army and Navy patients will receive care.

This center will be near a large city where the patients may not only enjoy such cultural pursuits as are provided by the theater and concerts but also, and much more important, may have a chance to find out whether they are fitted for employment in certain of the industries. Arrangements will be made to give the blind man opportunities to try various types of work in order to discover his likes and his adaptability. It is in this center that the newly blinded will learn the first things about taking physical care of themselves, eating, shaving, smoking, and such matters. They will begin the study of Braille. They will have the constant companionship of someone trained in the care of the blind, with psychiatrists available who will give them the proper approach to the new lives that they must now lead. The first depression must be overcome. A renewed faith that life is still worth living must be kindled. At this point the relatives must be educated in the proper attitude toward blindness. The demoralizing effect of demonstrations of pity must be clearly presented and strongly deprecated.

The time to be spent in this preliminary training center will vary greatly with the individual. One of our boys, blinded in this war, who had been a newsdealer before the war, was convinced that he could return at once to his home and take up his employment again. He was even optimistic enough to believe that he could make more of a success of it because he was blind! That is true courage. A man like that need stay only a very brief time at a training center. He can be discharged

from the Army, his pension, which is a generous one, started, and arrangements made for such further study as he may wish to take at home. The most important problem in his case may well be that of his home folks, to see to it that they do not let their pity for him be obvious, to encourage his independence, and to let him feel that he is still one of them as before, and has not become a person apart because of his lost vision.

On the other hand, there will be those who have been completely shaken by their sudden loss, for whom months of mental rehabilitation is necessary. Some will show a natural adaptation for certain lines of work that are open to the blind, others none at all. Braille is difficult. There are many who cannot learn it, but this applies more to the old than to the group of war blinded. However, it would be ingenuous to think that the man who never did care for reading even when sighted is going to be enthusiastic about the study of Braille. No matter how much one may desire it and strive to give some men the broader education to fit them for lives of usefulness, there will always be a considerable percentage who are destined to be porch sitters. With a good pension, probably more money than any of them ever had before, they are going to be satisfied to do nothing constructive. It is only to be feared that some of their relatives will seek to live on the same pension!

The ideal program for rehabilitation of the war-blind is immediate care for their injuries or eye diseases under the best possible supervision with psychologic aid at once by a psychologist trained in care of the blind. This step should be followed by transfer at the earliest possible moment to a center for the blind for preliminary rehabilitation, as described.

The arrangements planned for our soldiers and sailors up to this point are good. From here on the ideal is to discharge the

men to environments where they would have equal opportunities for social, occupational, and educational growth. Here our program falls down because we have no one national organization whose business it is to follow these men and look after their welfare. They are discharged with money in their pockets, each his own man to do as he likes. That is as it should be; but he returns, presumably to his home, where the only technical help that he will have in his further rehabilitation will be such as his state provides. In some states this is good, in many it is poor, and in some there exists practically none.

As Sir Ian Frazier points out, "Ultimately of course the After-Care Department became practically the whole of St. Dunstan's. . . ." Through this channel England has kept in constant touch with all of her war-blinded. It is their alma mater, their guide, counsellor, and friend, their point of reunion. A special dormitory is set apart for those returning to visit. This is all of vast importance to these men. To be sure the United States is far larger than Great Britain, but the principle is the same and it would seem that either through Government or private agency, or through both, some such organization should be established in our country, primarily or at least ultimately to include all of our blinded. Through this means there would be an adequate follow-up of a program well started by the Army, and undoubtedly this would be of inestimable value toward returning this group to a normal life.

Lawrence T. Post.

SELF-OBSERVATION OF RETINAL DETACHMENT

Patients are often skeptical regarding the extent to which physicians can sympathize with the symptoms and complaints of those to whom they minister. A fam-

ous western eye surgeon is reported to have stated that he never used on his patients any drug which he had not tried upon himself. There is room for argument that general adoption of such a rule might be beneficial.

It would naturally be out of the question to require every practitioner of a specialty to have personal experience of all that his patients endure in disease, whether medical or surgical. It may be supposed that, other things being equal, the most careful refractionists are those who have themselves suffered the inconvenience of uncorrected refractive errors. But, fortunately, few of us are called upon to encounter in our own persons the discomforts or tortures, the disabilities, the fears and hopes and disappointments associated with the onset, progress, and surgical treatment of glaucoma or retinal detachment.

The literature of ophthalmology presents a number of examples of self-observation in connection with eye disorders. The insidious development of glaucoma, and the process of adaptation to the blindness resulting from that disease, have been eloquently described by several ophthalmologists, notably Laqueur and Javal. There has been no dearth of description of the experiences connected with the gradual formation of cataract. Analogous studies have probably been published previously in relation to retinal detachment, although the present writer cannot just now lay hands upon any one of them.

An excellent description of personal experience with retinal detachment and its successful treatment comes now from the pen of a Brazilian colleague, identified to the world at large only by the initials "V. J.," but whose account is published with an introductory note by W. Belfort Mattos, of São Paulo, Brazil (*Arquivos Brasileiros de Oftalmologia*, 1943, volume 6, page 63).

"V. J.," having himself for years performed the diathermy operation for retinal detachment, was quite familiar with the symptomatology of the disease, and with the experiences of those who submitted to operation, as described by the patients. He is forty-five years old, and has ten diopters of myopia. He has had in the right eye two attacks of exudative choroiditis, which he attributes to a dental cause, and which have been treated focally and with subconjunctival injections of hypertonic sodium chloride.

In November, 1942, he suddenly developed a vitreous exudate in the left eye. This exudate improved quickly after attention to a dental granuloma, but V. J. noticed that in the upper outer sector of the visual field objects seemed to quiver slightly, and possessed a strange gleam as though covered by cellophane tissue. In the course of a few days this first symptom of detachment developed into a rapidly progressive narrowing of the visual field. Central vision had returned to normal, and the writer continued his daily practice of ophthalmology, including an operation for diathermy coagulation of retinal detachment.

V. J. records that he went to the office of his friend Pereira Gómez with the pupil dilated by homatropine. Looking in the appropriate direction he was able to place the eye so that the field of the examiner's ophthalmoscope included the probable site of the retinal tear, the point at which the patient had experienced his first symptoms of tremulous vision. The detachment was flat, with a V-shaped tear. V. J. says he "had waited all these days to confirm the rapid increase of the myopic retinal detachment, as distinguished from the slow and nonvarying detachment caused by choroidal tumor." The "cellophane tissue" reflexes and the phosphenes were no longer noticeable, but the narrowing of the visual field reached

almost to the macula. However, the vitreous exudate had disappeared and macular vision was still 0.8 with the myopic correction and under mydriasis.

The retinal tear was readily localized, corresponding to the field position 20 degrees upward and outward, and to the 65-degree level, and being 12 mm. distant from the limbus.

V. J. states that his greatest inconvenience at the time of operation was from lavage of the conjunctival sac and from the procedure of limbal localization. The retrobulbar injection, to which some patients object so strenuously, bothered him not at all. On account of the high myopia and the direction in which he was forced to look, in order to expose the operative field in the lower inner quadrant, he was able to follow with both eyes every step of the operation. Every time the fine electrode perforated the sclera the retinal stimulation was intense, producing a "heavenly paradise such as is imagined by children and the faithful; an enormous variety of lights of all colors, resembling a scintillating mother-of-pearl, clouded the whole vision. . . ."

At the end of the operation, he says, "I distinguished fingers with the operated eye, which cheered me considerably because the danger of an immediate intraocular hemorrhage was much in my mind." No step of the operation was painful.

Dealing with the fixed position required during convalescence, emphasis is laid by V. J. on the value, at such a juncture, of previous training in self-control. A surprising experience, not previously imagined, was "an exquisite subjective sense of surrounding objects, persons, and things . . . : distorted figures, with three or more arms and legs, . . . twisted bodies. . . . A drinking glass, for example, only resumed its natural form when I touched it. I made an effort to evoke agreeable

hallucinations and only succeeded in seeing the worst of the so-called futuristic paintings. . . . I judge that my preoccupation not to move my head or eyes was the cause of all the subjective phenomena. . . ."

V. J. found his most unpleasant experience in convalescence to be the necessity for maintaining immobility in bed, spending five days and nights in a single position being sometimes impossible. "I was only successful in remaining three days immobile in the bed and after that I passed the day in the chair and lay down only at night, making the change between these two positions very slowly without displacing the head from its ideal position." Sleep was always taken in right lateral decubitus.

After eighteen days V. J. resumed his ophthalmologic practice, with normal vision. He confesses that some of the rules usually imposed upon patients by himself and other oculists were disregarded, "not from indiscipline," but because he found them exaggerated. Whereas resting the eye and keeping the head immobile in the proper position are indispensable, "immobility of the bed does not help the patient at all if the operation did not close or block the retinal tear. . . . If the operation did not go well, the retina which at the first examination appeared perfectly attached begins to become detached after the first six or eight days. Hence the absolute necessity for determining the cause of the detachment, whether traumatic, myopic, syphilitic, tuberculous, and so on."

After seven months V. J.'s operated eye retained normal vision with correction, a visual field merely contracted a little in the upper outer quadrant by reason of the cauterizations, a few organized exudates in the vitreous, and no phosphenes or other subjective or objective symptoms pointing to recurrence.

W. H. Crisp.

BOOK NOTICES

WHEREAS I WAS BLIND. By Capt. Sir Ian Frazier. Clothbound, 168 pages. London, Hodder and Stoughton, Ltd. Price 8/6.

This is a very readable story of a man blinded in the first World War as a boy of 18, who would never let himself be discouraged but went forward to make of himself an outstanding figure in England.

He describes his sensations and reactions from the onset of his blindness through his varied career. He became assistant to Sir Arthur Pierson, who was director of St. Dunstan's in its early years, and, upon the death of Sir Arthur, in 1922, succeeded him as director of that institute. The author had multifarious interests: From the directorship of St. Dunstan's he was elected to Parliament, where he served several terms, always acting in the interests of the blinded. He later had a connection with the British Broadcasting Company.

The book is valuable from many points of view, perhaps foremost of which is the reaction of the individual to blindness. It is a good directive for those who have to do with the rehabilitation of the blind. This subject is particularly pertinent in these days when the number of our war-blinded is steadily increasing. The book also gives an interesting account of the development of St. Dunstan's, and points out the important sphere of influence that this organization has, its greatest value being in its Aftercare Department. The volume will be of value to all ophthalmologists because they have frequently to deal with the blind individual, and their contacts with the patient in the early stages of his blindness will be important in coloring his entire future.

Lawrence T. Post.

STRABISMUS, ITS ETIOLOGY AND TREATMENT. By Oscar Wilkinson. Second Edition; 369 pages; cloth binding; illustrated. Boston, The Meader Press. Price, \$4.00.

This edition of "Strabismus" is presented by Dr. Oscar Wilkinson in collaboration with Dr. Richard W. Wilkinson. The first 115 pages are devoted to the history of strabismus, the theories regarding its etiology, and a discussion of the physiology of the ocular muscles and of the physiology of vision. The second section of 75 pages is devoted to the types of strabismus and the methods of measuring the deviations. The third section of 170 pages is divided into the non-operative and operative treatment of squint. The chapter on Orthoptics has been rewritten and demonstrates the usefulness of the amblyoscope in diagnosing and treating squint. The chapter on Operative Treatment emphasizes the importance of accurate measurements in diagnosis and their value in selecting the most desirable type of surgery. Excellent illustrative cases with histories and photographs are shown in the last chapter.

The authors have presented clearly and concisely a great amount of controversial material. At the same time their opinions, choice of methods, and their results have been recorded.

William M. James.

CORRESPONDENCE

TYPE FOR INCOME-TAX INSTRUCTIONS

January 19, 1944

To the Editor:

In the last few months many of my elderly patients, and even some of the younger ones, have complained to me bitterly about the illegibility of the type in which the various income-tax blanks, and

particularly the "Instructions" which accompany them, are printed. I have therefore written to a Congressman friend asking him to see to it that no matter shall be printed on either blanks or the "Instructions" in smaller type than 10-point single-leaded. My Congressman friend replies that the request appears to him perfectly reasonable and that he will do his utmost to see that, in the pending income-tax reform-bill, the suggested requirement shall be incorporated.

To me it seems especially fitting and proper that the requirement in question should be backed by the medical group whose function and duty it specially is to safeguard, so far as possible, the eyes of the nation. The present moment, too (when both houses of Congress are in session and earnestly considering such a reform of the income-tax law as will enable at least ordinary people, engaged in ordinary business, to fill out their blanks correctly by the exercise of ordinary common sense), also seems to me the particularly appropriate time for seeing to it that ordinary people with ordinary eyes shall be able to see for themselves just what the requirements are which they, under very heavy penalties, are called upon to meet.

Will not, therefore, each and every ophthalmologist write three letters—one to his congressman and one to each of his U. S. senators, urging him to work for the adoption in the pending income-tax bill of the requirement that nothing on the income-tax return-blanks or on the "Instructions" explaining such blanks shall be printed in smaller type than 10-point single-leaded?

This matter should be attended to now. Delay would be fatal to the idea.

Your sincerely,
(Signed) Thomas Hall Shastid.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

1

GENERAL METHODS OF DIAGNOSIS

Costi Garcia de Tuñón, Carlos. Presentation of a new umbralometer. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, July, pp. 114-122.

The author's apparatus, illustrated only schematically in the article, includes a four-volt lamp, a battery with variable resistance, a collimator, a pair of Nicol prisms, and the necessary supports and other accessory details. By rotation, the Nicol prisms serve as a means of obscuration, which reaches its zero point with complete crossing of the prisms. The advantages claimed for the apparatus are: continuous control of the intensity of the current and of the mechanism of obscuration; elimination of the factor of accommodation; the possibility of making observations in the presence of low visual acuity; and the basing of the measurements, not upon light perception, but upon the "minimum perceptible," which affords greater sensitivity and greater rapidity of investigation. (2 illustrations.)

W. H. Crisp.

Craik, K. J. W. Specifications for dark-adaptation tests. *Brit. Med. Jour.*, 1943, May 22, p. 632. (See Section 10, Retina and vitreous.)

Drews, L. C. Further observations on autofunduscopy (auto-ophthalmoscopy of Eber; Purkinje figure of Walker). *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1143-1154; also *Trans. Amer. Ophth. Soc.*, 1942, v. 40, p. 370. (2 drawings, references.)

Krimsky, Emanuel. Graphic representation of binocular findings. *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1199-1204. (7 graphs.)

Oak, Lura. The Massachusetts vision test, an improved method for school vision testing. *Amer. Jour. Public Health etc.*, 1942, v. 32, Oct., pp. 1105-1109.

Considerations on the system of testing children's eyes in Massachusetts schools, regarding the inadequacy of Snellen test type, as to the proper test-type distance, and as to the type of illumination led the author to the conclu-

sion that the validity of the test might be increased through selection and training of qualified persons, the reliability of records being further increased by improvements in material and methods with a view to minimizing opportunities for memorization and to calibrating a standard of illumination upon the charts. The new method now available for general use is designed to bridge the gap between present inadequate provisions and the time when the eyes of all children will, it is hoped, be examined by qualified eye specialists. Administration of the test requires an average time of $2\frac{1}{2}$ minutes for children eight years of age or older. The test kit consists of the standard Luckiesh-Moss illuminator, the improved form of Snellen test type, a house chart mounted on a frame with an electrical tester, spectacles with plus spherical lenses, others with Maddox rods, and a central switch for controlling the lights. It further contains tests for latent hyperopia and muscle imbalance.

Melchior Lombardo.

Ramsay, A. M. The ophthalmoscope in clinical medicine. *Brit. Med. Jour.*, 1943, June 5, p. 685.

With the aid of the ophthalmoscope the clinician is able to observe the physiologic and pathologic processes in the eye. Especially the effects of a disordered metabolism on the cardiovascular system can be detected at the earliest onset. The information thus gained by the clinician may be likened to the reports obtained from the laboratory. Like laboratory reports, the ocular findings can be properly evaluated only when they are correlated with general symptoms of the disease.

THERAPEUTICS AND OPERATIONS

Bertotto, E. V. Evipan-sodium in ocular surgery. *Anales Argentinos de Oft.*, 1942, v. 3, Oct.-Nov.-Dec., p. 204.

The use of evipan and its advantages in ocular surgery are discussed. The author's experience with one case was satisfactory. Eugene M. Blake.

Borak, J. X-ray therapy of inflammatory and neoplastic diseases of the eye. *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1170-1174. (11 figures.)

Fleming, Norman. Iontotherapy (ionic medication, iontophoresis, ionisation) as an aid in ophthalmic therapeutics. *Brit. Jour. Ophth.*, 1943, v. 27, Aug., pp. 354-367.

Poor results obtained by the old methods of iontotherapy are blamed upon too strong currents, too strong solutions and too long applications. An apparatus is described and illustrated in which the power is derived from small batteries, ensuring that the milliamperemeter needle never indicates more than two milliamperes. The instrument is so constructed that positive ions such as calcium and zinc are introduced into the eye, and it is provided with a reversing switch for introducing negative ions such as salicylates.

Cases of conjunctivitis are reported, both acute and chronic, in which iontotherapy gave excellent results. Corneal ulceration and herpes ophthalmicus, as well as iritis, episcleritis, and scleritis, also respond favorably to iontophoresis. Also reported are a case of retrobulbar neuritis and one of embolism in which the outcome of treatment with ionic medication was satisfactory. The application used most often was six parts of calcium chloride (1 to 500) with one part of adrenaline hydrochloride (1 to 10,000). Treatment to the eye itself is usually not given for more than two minutes; to the everted eyelids for not more than one and a half minutes; and to the closed lids for not more than five minutes. A small quantity of zinc sulphate (1 to 400) is added to the calcium solution when there is loss of epithelium. Silver nitrate (1 to 1,000) or soluble prontosil (1 to 10,000) is added where a powerful antiseptic is required. Atropine, acetylcholine, histamine, quinine, eserine, pilocarpine, iodides, salicylates, and other drugs may be used.

The principal feature of treatment by iontotherapy is reduction of congestion and so of inflammation generally. The claims of success in treatment of deep as well as of superficial inflammation are based on experience gained in the treatment of about one thousand cases during the past ten years. Iontotherapy is likely to be of particular value in the treatment of war casualties. (4 figures, references.)

Edna M. Reynolds.

Frey, Guernsey. "Through evil, good." *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1208-1209.

Gallo, L. A. Use of dental absorbent rolls in ocular surgery. *Anales Argen-*

tinios de Oft., 1942, v. 3, Oct.-Nov.-Dec., p. 210.

Gallo employs dental absorbent rolls in ocular surgery and recommends them to others. They come in several sizes and are sterilized by placing in oxycyanide solution, 1 to 1000, to which is added 50 drops of formol.

Eugene M. Blake.

García Miranda, Antonio. Importance of the slitlamp in the study of starvation conditions. *Arch. de la Soc. Oft. Hisp-Amer.*, 1942, v. 1, July, pp. 108-113. (See Section 17, Systemic diseases and parasites.)

Hughes, W. L. Water bath for maintaining proper temperature of eye-irrigation solutions. *Amer. Jour. Ophth.*, 1943, v. 26, Oct., pp. 1089-1091. (3 illustrations.)

Paula Santos, B. On the anti-infectious action of the sulfanilamides in ophthalmology. *Arquivos Brasileiros de Oft.*, 1943, v. 6, April, pp. 25-37.

The author, whose article is accompanied by five pages of bibliography, reviews the literature of the subject and considers the three modes of introduction of these drugs, namely the parenteral, the oral, and the local. With some other writers, he is disposed to take a conservative view as to the benefits to be derived in trachoma. In this disease he regards the action of the sulfanilamides as relating particularly to secondary infection, and only indirectly to the trachoma itself. He finds that, as indicated by the slitlamp, the limbal and conjunctival follicles are reduced but do not disappear. In some exceptional cases, treatment for as long as a year failed to yield results.

W. H. Crisp.

Pokrovsky, A. I. **Remarks on ocular war surgery.** *Viestnik Oft.*, 1943, v. 22, pt. 2, p. 3.

This is a plea for the more extensive use of fat implantation in plastic surgery of the lids. Although first proposed by Silex in 1896, its use is not so widespread as the author believes it deserves to be. It is particularly indicated in retracted scars of infected wounds of the lids, in which the skin although not shortened is drawn in and adherent to the periosteum. The deformity of such subcutaneous cicatrices can be relieved by freeing the skin from the periosteum and interposing between it and the subcutaneous tissue a layer of fat. The cosmetic appearance of disfiguring cutaneous transplants can be improved by padding them with a layer of fat. Four cases illustrating the effectiveness of fat transplantation in such cases are briefly reported.

Fat implantation is also useful in bony defects of the orbit caused by orbital injuries, or slowly growing orbital neoplasms. The retraction of the lids caused by such defects can be remedied by implantation of fat. The fat fills in the defect, does away with the retraction of the cicatrices, and improves the cosmetic appearance of the lid folds. It should be kept in mind that fat has no resistance to infection, and its implantation should not be attempted until infection has run its course.

The author also makes a plea for careful primary repair of lid injuries. While the general rule is to introduce no sutures in field stations, in injuries of the lids this rule does not apply. The lids are very resistant to infection, and primary sutures restoring the normal position and contour of the lids will save the injured person many subsequent plastic procedures. The conjunc-

tiva too is resistant to infection; and in injuries of the orbit and eyeball, requiring enucleation of the eyeball, the orbital and conjunctival wounds should be properly coapted and repaired so that an artificial eye may be worn subsequently. The author deplors the frequent performance of enucleations without attention to orbital and conjunctival wounds, so that symblepharon and obliteration of the conjunctival sac necessitate subsequent operations.

Another procedure advocated by Pokrovsky is that of multiple conjunctival incisions parallel to the lid margin for the enlargement of a shrunken conjunctival sac. After such incisions the introduction of a large prothesis lubricated with cod-liver oil leads to the epithelization of the conjunctival wounds, with permanent enlargement of the socket.

Post, L. T., and Robertson, E. N. **Intravenous pentothal-sodium anesthesia in ophthalmology.** *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1155-1163. (One table, references.)

Scott, G. J. **Effectiveness of sulfonamides when applied locally to the eye.** *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 3-13.

The author describes the effectiveness of the sulfonamides when used locally in ophthalmology as reported by research workers. With this as a basis he discusses the clinical use of the drugs. The sulfonamides are bacteriostatic except in very high concentration. The general defense mechanism of the body must be stimulated by specific or nonspecific measures. Oral or parenteral administration is indicated in infections of the orbit, lids, or conjunctiva, which can be reached through the blood stream in a concentration of 5 to 10 mg. per 100 c.c.

In treatment of an avascular structure such as the cornea the concentration of the drug must be aided by some form of local application. The value of purely local treatment is in prevention of infections of the eye in first-aid treatment of industrial injuries. In local treatment of acute infections, satisfactory results have been obtained only where the local applications were used at hourly, half-hourly, or even 15-minute intervals. (5 tables, 2 illustrations, references.) Beulah Cushman.

Sorsby, Arnold. **Ocular pharmacology of the sulfonamides.** Trans. Ophth. Soc. United Kingdom, 1942, v. 62, pp. 15-33.

From a review of the experimental use of the sulfonamides, the author concludes that clinically sulfapyridine seems the most effective in the eye. The dosage should be calculated for each patient on the basis of body weight, to maintain the optimum concentration of 10 mg. per 100 c.c. in the blood. The ocular complications of sulfonamide therapy are transitory myopia, retinal hemorrhages, optic neuritis, and conjunctival reactions. (Bibliography.) Beulah Cushman.

Thygeson, P., and Stone, W. Jr. **Sulfonamide therapy of ocular infections.** New York State Jour. Med., 1943, Aug., p. 1409.

Sulfadiazine, because of its low toxicity, is the drug of choice for oral administration in most ocular infections. The infections responding rapidly to oral sulfonamide therapy included gonorrheal, conjunctivitis due to trachoma, acute dacryocystitis, and corneal ulcers due to streptococcus hemolyticus and pyocyanus. Slow in response were blepharitis, conjunctivitis, and corneal ulcers due to staphy-

lococcus aureus. No response was found in tuberculosis, hemolytic streptococcus infections, pemphigus, virus infections, and sympathetic ophthalmia.

Local sulfonamide therapy is employed with success in superficial infections including blepharitis, conjunctivitis, and corneal ulcerations. Sulfathiazole ointment in blepharitis and conjunctivitis and sulfadiazine powder in corneal ulcerations seem to give the best results. Combined oral and local therapy should be used in severe infections. (3 tables.)

Gertrude S. Hausmann.

Von Sallmann, Ludwig. **Penicillin and sulfadiazine in the treatment of experimental intraocular infection with pneumococcus.** Arch. of Ophth., 1943, v. 30, Oct., pp. 426-436.

Various types of pneumococcus were inoculated into rabbit eyes and the results of treatment with sulfadiazine and penicillin were observed. It was found that infections caused by D. pneumoniae type III and type X were not stopped or were only temporarily improved by intensive local and systemic treatment with sulfadiazine. Severe intraocular infection by types III, X, and VII was usually checked by local treatment with penicillin. Infections caused by injection of types III and X with simultaneous injury to the lens capsule were treated successfully with penicillin in most instances. The iontophoretic introduction of the penicillin salts in 0.1 and 0.25 percent solutions was occasionally more effective than the corneal bath of a 0.25 percent solution. Repeated applications of a 0.25 percent solution by iontophoresis caused large abrasions of the cornea which healed without opacity. Strains of pneumococcus types VI, XIV, XIX,

and XXIII showed in vitro the same sensitivity to penicillin as the strains used in the rabbit experiments. (Bibliography.) John C. Long.

Wiener, M. Transplantation of preserved tissue in ophthalmic surgery. Jour. Michigan State Med. Soc., 1943, v. 42, Jan., p. 53.

The author presents a very interesting detailed account of the subject as regards corneal and conjunctival tissue. He describes in detail his technique of conjunctival implantation. He believes that preserved heterogeneous implants may be of value in plastic surgery wherever mucous membrane is needed.

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Burian, H. M. A visual phenomenon related to binocular triplopia. Amer. Jour. Ophth., 1943, v. 26, Oct., pp. 1084-1086. (References.)

Burton, E. W. Progressive myopia: a possible etiologic factor. Trans. Amer. Ophth. Soc., 1942, v. 40, pp. 340-354.

Myopia is defined and the various theories advanced in the literature are reviewed. Particular emphasis is placed on the mechanical theories of myopia. The role of the orbicularis muscle in progressive myopia is discussed and a method of clinically testing the strength of the muscle is presented. Axial myopia was experimentally produced in young rabbits by mechanically constricting the globe at its equator with a tight silver wire. The intraocular pressure was thus elevated a reasonable amount, producing anteroposterior elongation of the eyeball.

The author concludes that frequently myopes who are undercorrected or who wear no correction at all resort to the habit of squeezing the eyelids together in order to make the diffusion circles smaller. When myopia is fully corrected, distant vision is distinct and there is less tendency to squeeze the lids together. Fully corrected myopia seems to show less tendency to progress than that which is only partially corrected. Contraction of the orbicularis muscle probably causes an increase in intraocular pressure which, if maintained over a long period of time, may cause stretching of the sclera not only in the very young, but also in older individuals if the sclera is already weakened. Elongation of the anteroposterior diameter of the eyes of rabbits can be produced by increasing the intraocular pressure. (7 illustrations, bibliography.)

David O. Harrington.

Elder, J. H. Effectiveness of vitamin A in the treatment of defective color vision. Science, 1943, v. 97, June 18, p. 561.

Sixteen college students who had defective color vision were given 25,000 units of vitamin A daily for eight weeks. One of the students took 250,000 units daily. Fourteen students, including the one just mentioned, showed no improvement whatsoever. Two students achieved perfect scores and passed the Army-Air-Corps tests. These two, however, had very slight defects.

A second experiment was made with 58 subjects who received 50,000 units of vitamin A every second day for eight weeks and were obliged to swallow the capsules under supervision. Of the 41 persons who finished the course of treatment, not one showed any im-

provement. The author draws the conclusion that vitamin A fails to produce any significant improvement in color sensitivity, although in a negligible few instances, where the defects of color vision are of minor degree, it may improve the color vision slightly.

Judd, D. B. **Color-blindness and the detection of camouflage.** *Science*, 1943, v. 97, June 18, p. 544.

The author analyzes the conditions under which a color-blind and a color-screened normal observer respectively could detect a camouflaged position.

R. Grunfeld.

Low, F. N. **Studies on peripheral visual acuity.** *Science*, 1943, v. 97, June 25, p. 586.

Peripheral visual acuity was measured on the perimeter by the use of Landolt's broken circles with breaks of various sizes. The test objects were placed at 30 and 60° and at the four points of the compass. The size of the break in the smallest circle successfully identified four times in succession was scored. The peripheral visual acuity thus measured was found to be an independent factor. It did not correlate with age, sex, central visual acuity, or color vision. The second eye, generally, scored better than the first. A 6-percent improvement was recorded when the test was repeated and a 16-percent gain noted when the test was taken for the third time. This indicates that peripheral visual acuity can be trained.

R. Grunfeld.

Luckiesh, M., and Moss, F. K. **Comparison of a new sensitometric method with usual technics of refraction.** *Arch. of Ophth.*, 1943, v. 30, Oct., pp. 489-493.

This sensitometric method of refraction

is a subjective method in which the dioptric power producing maximal visibility is determined with the Luckiesh-Moss sensitometer. In this method relative accommodation is avoided by the elimination of all adequate optical stimuli for accommodation from the entire binocular field. Satisfactory control may not be obtained by the fogging method, as the stimulus for relative accommodation increases as the plus power is decreased. The sensitometric method involves binocular parafoveal stimuli sufficient to insure convergence at a point in the plane of the test object. However, it has been shown that this is an inadequate stimulus for relative accommodation. In the usual methods of testing, monocular and foveal stimuli for accommodation as well as for convergence are present.

Sensitometric observations have demonstrated that the normal eye is myopic in the absence of stimuli for relative accommodation and that it may become emmetropic when such stimuli are present. In formulating a dynamic definition of emmetropia, the authors state that this condition exists when all points within the range of habitual near vision and the retinas are conjugate without the exercise of relative accommodation (and with the static addition), while more distant points may become conjugate by the exercise of negative relative accommodation.

Sloane, A. E. Refraction clinic. *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1212-1215.

Stocker, F. W. Pathologic anatomy of myopic eye with regard to newer theories of etiology and pathogenesis of myopia. *Arch. of Ophth.*, 1943, v. 30, Oct., pp. 476-488.

The usual pathologic changes encountered in high myopia are discussed, together with the detailed findings in a myopic eye of a fifteen-year-old boy. Thinning of the posterior pole of the globe has been found almost regularly in severe myopia, and a flat arrangement of the scleral fibers is generally found in such cases of thinning. Temporal conus is usually present but does not generally appear until the second decade. Along with temporal conus in cases in which the retina overlaps the choroid toward the optic disc, the nerve fibers corresponding to the most temporal part of the optic nerve turn around the edge of the retina and form a "temporal nerve-fiber loop". Supertraction of the retina over the nasal part of the disc is often found in high myopia. Atrophy of the choroid occurs but usually does not develop until later in life, at which time the progress of the myopia is relatively stationary. Retinal changes appear to be largely associated with atrophy of the choroid.

The conventional theory of the causation of myopia considers that the sclera, choroid, and retina are stretched by some force. The author adheres to the theory of Vogt that the retina is the determinative factor in the size of the eye. If the retina has a stronger tendency to grow than the sclera, the latter may be stretched. The "push" delivered by the developing retina is to be considered in the biological rather

than in the mechanical sense. It has been shown pathologically that in young myopic eyes there may be considerable stretching of the sclera while the retina remains normal. Retinal changes develop late and are secondary to choroidal atrophy. It seems possible that each coat of the eye has its own inherited potential of growth. In the majority of persons, there exists enough coördination of growth to bring about the development of an eye which is emmetropic or nearly so.

John C. Long.

Vishnevsky, H. A., and Flekkel, A. B. A study on the recognition of colored signals by persons with defective color vision. *Viestnik Oft.*, 1943, v. 23, pt. 1, p. 16.

Defective color vision was found in 8 to 9 percent of applicants for schools of aviation, in 1 percent of the flying personnel and aviation cadets, and in 14 percent of applicants rejected because of ocular defects. In order to determine to what extent it would be possible to utilize color defectives in aviation, 41 persons with color defects were given a laboratory examination and a practical test on recognition of the colored signals which are very important in night flying. Colored signals are used to avoid collision in formation flying, to make contact with the ground, and to mark interferences in landing. The test objects were colored flares used in aviation, aerial navigation lights, and colored signals observed from the ground and from the air. The laboratory examination consisted of tests with the Stilling, Ishihara, and Rabkin plates, and with the Nagel anomaloscope. The test with flares was carried out at night on a river bank. The recognition of colored signals on the ground was recorded

from a distance of 1,000 meters, and then at intervals of 100 to 500 meters. Recognition in flight was tested at 1,000, 800, and 600 meters. The signals were white, red, yellow, green, and blue.

The data show that recognition of green, red, and yellow flares is difficult even for normal trichromates, three out of nine calling yellow flares red. Among persons with anomalous deuteranopia the errors were very high, only two out of 29 giving the correct answers. Since each colored flare has a definite meaning, confusion is obviously dangerous in military aviation. Recognition of colored signals is very poor in anopes and anomalous deuteranopes, even at a distance of 500 to 600 meters.

The conclusions are that classification of defective color vision is difficult with colored plates, and can best be done with the anomaloscope. The correlation of the laboratory data and practical tests shows that the largest number of errors is made by anopes. Persons with identical defects in color vision varied in their responses to the practical tests. Recognition of aviation signals differs from railroad and automobile signals in the small visual angle under which the lights are seen and in the required rapidity of recognition. Proper response to colored signals in aviation requires correct recognition and identification of the color.

OCULAR MOVEMENTS

Allen, T. D. Eyes right and down—not eyes down and right. *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1209-1210.

Fralick, F. B. The treatment of amblyopia. *Amer. Jour. Ophth.*, 1943, v. 26, Nov., pp. 1195-1197.

Nugent, O. B. The management of strabismus. *Jour. Iowa State Med. Soc.*, 1942, v. 32, Dec., pp. 533-537.

An attempt is made by the author to classify the cases of strabismus according to age of the patients and a system of treatment to be applied to each age group, as follows: (1) In patients from one to six years of age, correction of error of refraction under cyclopegia, daily occlusion of the good eye, attention to avitaminosis, orthoptics; (2) in patients from 7 to 15 years, correction of error of refraction under cyclopegia, occlusion of functioning eye, orthoptics; (3) in patients from 15 to 30 years of age, correction of refraction, orthoptics, surgery, postoperative orthoptics; (4) In patients 30 years of age and beyond, refraction manifest or cyclopegic, surgery. The writer discusses various surgical methods, and describes the technique which he favors, namely, recession with a control suture. A vertical 10-mm. incision is made in the conjunctiva with iris scissors over the point of attachment of the muscle. The muscle is dissected from conjunctiva and Tenon's capsule for about 5 mm., and is then cut loose from the globe with the same iris scissors while it is steadied with a muscle clamp. For control suture a no. 4 doubly-armed silk thread is used, being placed through the muscle tendon in such a manner as to hold the muscle flat against the sclera. The cut edges of the conjunctiva are sutured. The eyes are inspected to determine their relative position, using the corneal reflex from the light of an electric ophthalmoscope; and other surgery is performed on the same or the second eye if necessary. The control suture is then adjusted so as to produce parallelism between the visual axes of the two eyes, using a Maddox rod in front of the

unoperated eye while the patient wears his correcting glasses. A surgeon's knot is made and the loose ends of the control suture are fastened on the patient's forehead. Readjustment is repeated if necessary, and the suture is removed on the fourteenth day. References, 8 illustrations.) M. Lombardo.

CONJUNCTIVA

Browning, S. H. Tuberculosis of conjunctiva. *Proc. Royal Soc. Med.*, 1943, v. 36, June, pp. 407-408.

The author presents the case of a 29-year-old female patient who had a hard, punched-out ulcer on the left lower eyelid, sections of which showed giant-cell systems and acid-fast bacilli. Guinea-pig inoculation was positive. In the accompanying discussion, it was brought out that these cases of human-type tubercle of the lids were usually not part of a generalized tuberculosis. The value of ultraviolet and heliotherapy, as well as of sanatorium régime, was also stressed.

Gallaher, Clinton. A study of trachoma with a report of 318 cases, 233 treated with sulfanilamide. *Jour. Oklahoma State Med. Assoc.*, 1943, v. 36, May, p. 185.

Basing his opinion on the great number of trachoma patients treated with sulfanilamide and observed for an appreciable period, the author believes that although sulfanilamide may not be beneficial in every case of trachoma one can be assured that it will be of great benefit in over 90 percent of the cases. In cases of subepithelial follicles and beginning pannus the treatment consisted of peroral administration of sulfanilamide only. In cases with papillary hypertrophy and advanced pannus, sulfanilamide was given by mouth and the case was observed for three to four weeks, after which grattage was done. This was followed by local administration of one-percent sulfanilamide in Ringer's solution, and at bedtime 0.5-percent zinc ointment was applied. If phlyctenules or acute keratitis complicated the picture, vitamin A (afaxin in oil) was instilled. Sulfanilamide may be given with reasonable safety to ambulatory patients. R. Grunfeld.

Goldenberg, A. Z. Therapy of gonoblenorrhoea with albucide. *Viestnik Oft.*, 1943, v. 23, pt. 1, p. 29.

This is a report of a clinical study on the local use of sodium acetyl sulfanilamide in gonoblenorrhoea. Because the concentration of sulfanilamides administered by mouth is lower in the conjunctiva than in any other tissue, the author doubts the effectiveness of its oral administration in conjunctival infections; in addition the sulfonamides are quite toxic in infants, who form the majority of patients with gonoblenorrhoea. Sodium acetyl sulfanilamide is soluble in water to a 40-percent concentration. A 30-percent solution was tested on the eyes of rabbits in the laboratory; it was instilled every thirty minutes for four hours and found harmless. The pure powder instilled four times at hourly intervals produced

only a slight transitory conjunctival injection, without any corneal changes. Clinically this therapeutic agent was tried in nine cases of gonoblennorrhea. The conclusions are that this preparation in a 10 to 30 percent concentration is very effective in gonoblennorrhea acquired during delivery; that in such cases the conjunctival sac was sterile after 2 to 3 days treatment; and that early corneal infiltrates absorbed promptly, the ulcers becoming clean and covered with epithelium. The local instillation of this drug caused no toxic symptoms.

The drug was less effective in gonoblennorrhea acquired after birth. In some cases the conjunctiva became sterile in a few days, in others it took 10 to 15 days, and in some the deeper layers of the conjunctiva contained involution forms of the gonococcus for as long as 25 days. It appears therefore that while this agent affects the gonococcus profoundly, it produces complete sterilization only after prolonged instillation. The effectiveness of this drug is insignificant in gonoblennorrhea of adults, even in moderately severe cases.

MacCallan, A. F. Tumor of conjunctiva simulating tubercle due to trachoma. Trans. Ophth. Soc. United Kingdom, 1942, v. 62, pp. 79-82.

A man 32 years of age had a tumor of the conjunctiva of the upper lid, with irregular "hob-nail" surface which was called trachoma. Such an unusual type has been described not infrequently in the Baltic coast region. After the surface growth was treated with beta radiation, the mass disappeared very promptly. (2 illustrations.)

Beulah Cushman.

Schnee, I. M. Membranous inflammation of oropharynx, nose, and con-

junctiva due to sulfathiazole. Brit. Med. Jour., 1943, April 24, p. 506.

Membranous inflammation of the conjunctival, nasal, pharyngeal, buccal, and laryngeal mucosa appeared on the fifth day of sulfathiazole therapy in one-gram doses every four hours, four times daily, for an upper respiratory infection. Cultures for diphtheria were negative. Staphylococci and *M. catarrhalis* were found. Wassermann and urine tests were negative. When first administered, the drug caused deferescence and relief of symptoms, but the fever returned when the complicating membranous changes appeared. On the ninth day of sulfathiazole therapy the drug was discontinued, and in ten days all the lesions had disappeared.

CORNEA AND SCLERA

Ballantyne, A. J. "White rings" in the cornea (G. Coats). Trans. Ophth. Soc. United Kingdom, 1942, v. 62, pp. 83-102.

Macroscopic and microscopic examinations of a "white ring" of the cornea are described. The ring was composed of discrete, closely set, apparently globular, chalky-white bodies measuring 1.5 micra. The bodies were refractile rather than obstructive, and were grouped around a central area. They were somewhat irregular in shape and of waxy appearance, and were situated between the epithelium and Bowman's membrane, the base line of the epithelium extending over the cavities. Chemical analysis indicated some calcium salt. In dealing with etiologic factors the author mentions congenital and traumatic cases and those arising from some antecedent intraocular disease. (12 illustrations, references.)

Barrenechea, S., Contardo, R. and Arentsen, J. Riboflavin in the treatment of various corneal affections. *Ophth. Ibero Amer.*, 1943, v. 4, no. 4, pp. 405-421 (in Spanish), pp. 421-434 (in English).

The authors discuss the physiologic role of riboflavin and the symptoms of ariboflavinosis, especially as regards the eye. From these considerations, and from treatment of 109 patients, they draw the following conclusions: Vascularization of the cornea is a mechanism of compensation for obtaining the oxygen of hemoglobin when it cannot be furnished by natural riboflavin. The first dose should be high, 3 to 5 mg. given intravenously, dropping afterward to 2 mg. daily for one week. Corneal ulcer sometimes becomes negative to fluorescein within 12 or 14 hours. Failures with riboflavin are attributed to inadequate dosage, lack of intestinal absorption when the preparation is given by mouth, systemic lack of pantothenic acid, excessively severe ariboflavinosis, or active tuberculosis. Parnechymatous keratitis also appeared to be benefited by a riboflavin dosage of 5 or 6 mg. daily.

W. H. Crisp.

Daily, R. K. Familial corneal dystrophy. *Texas State Jour. of Med.*, 1943, v. 39, May, p. 34.

The author records five cases of corneal dystrophy occurring in one family. One pedigree chart and five black and white drawings are included. The corneal dystrophy of the family belonged to the granular type. A short review of the characteristics of the three types of corneal dystrophy is given.

T. M. Shapira.

Gregory, M. K. The ocular criteria of deficiency of riboflavin. *Brit. Med. Jour.*, 1943, July 31, p. 134.

Early ocular signs of riboflavin deficiency are discussed. Corneal vascularization is found to be a more reliable sign than the circumcorneal injection which has lately been given more attention.

In the corneal vascularization, the vessels are arranged streamer-like around the cornea in both eyes. The normal anatomy of this area of the eye is discussed, and other pathologic conditions which might present similar pictures are mentioned.

Gertrude S. Hausmann.

Lazarev, E. G. The absorption of corneal opacities of various etiology. *Viestnik Oft.*, 1943, v. 22, pt. 1, p. 7.

This is a preliminary report on a procedure designed to hasten the absorption of corneal opacities. In his work with corneal transplantation Filatov noticed the beneficial effect of the operation on the cornea of the host; the opaque cornea around the transplant became more transparent. Filatov attributed this phenomenon to the action of substances which develop in the transplanted cadaver-cornea during the period of its conservation on ice. Lazarev noticed the same effect in a case of transplantation of fresh cadaver-cornea. It then occurred to him that perhaps the beneficial effect was due not to the action of the transplanted cornea, but to excision of a segment from the opaque cornea, thus opening a drainage route for deleterious substances accumulated within the cornea. Lazarev believes that in cases of deep keratitis the intact epithelium obstructs the evacuation of exudates accumulated within the cornea, and that the clearing of corneal opacities can be hastened and promoted by excision of a superficial strip of cornea. He finds support for this belief in the fact that corneal diseases with destruction of corneal

epithelium run a more rapid clinical course than corneal diseases in which the corneal epithelium remains intact. With this idea, in seven cases of tuberculous or luetic parenchymatous keratitis he excised a strip of cornea 2 by 4 mm. in size, with visual improvement in all cases. He subsequently modified the procedure. Now, instead of completely excising a flap, it is left attached at its upper border, hanging from the cornea like an apron. (Illustration.)
Ray K. Daily.

Loewenstein, Arnold. **Some contributions to the lipoidal pathology of ocular tissue.** Trans. Ophth. Soc. United Kingdom, 1942, v. 62, pp. 159-167.

The author describes two groups of fatty dystrophy of the cornea. The primary is of unknown origin and shows symmetrical bilateral interstitial involvement with no sign of inflammation or vascularization. The secondary follows such diseases as keratomalacia, herpes, scars, dermoids, and degenerative corneal conditions. The collection of fat is due to a disturbance in the local metabolism where the oxidizing power is not sufficient to oxidize the high quantity of blood fat. (8 illustrations.)
Beulah Cushman.

Stone, Simon. **Vitamin E (wheat germ oil) in the treatment of interstitial keratitis.** Arch. of Ophth., 1943, v. 30, Oct., pp. 467-475.

It has been demonstrated that wheat germ oil has a beneficial effect on the absorption of tissue exudates as observed in cases of arthritis deformans, in cases of congenital nonobstructive hydrocephalus, and in selected cases of pseudohypertrophic muscular dystrophy. These observations have led to its use in resistant cases of interstitial keratitis. Ten patients with luetic interstitial

keratitis were treated. All had received ample antisyphilitic therapy and six had received fever therapy. The vitamin therapy consisted in the administration of vitamin-E concentrates combined with vitamin-B complex. All ten of the cases treated, even some with long-standing opacities, showed definite improvement.

This combination of vitamin E with B complex hastens the absorption of corneal exudates and opacities. It also prevents further organization of scar tissues of the cornea and reduces excessive capillary permeability. Riboflavine is thought to enhance the action of vitamin E by its beneficial effect on the oxidative processes of the cornea.

It is suggested that, in addition to antisyphilitic therapy, all patients with interstitial keratitis be given a mixture of vitamin E with B complex. Artificial fever is of value in preventing relapses and in producing a more rapid subsidence of acute symptoms.

UVEAL TRACT, SYMPATHETIC DISEASE AND AQUEOUS HUMOR

Meyer, G. P. Syphilis in relation to the iris and uveal tract. *Jour. Med. Soc. New Jersey*, 1943, v. 40, Feb., p. 55.

The author presented this paper as a part of a symposium on syphilis and its relation to eye, ear, nose, and throat. He discusses the incidence of syphilis, roseola of the iris, secondary and tertiary and recurrent syphilitic iridocyclitis, congenital syphilis of the uvea, and diagnosis and prognosis of uveal syphilis. Interesting is a quotation by the author from Weiss, who states that 55 percent of all iritis is luetic.

T. M. Shapira.

Rabinowicz, M. G. Blood changes in threatened sympathetic ophthalmia. *Viestnik Oft.*, 1943, v. 25, pt. 1, p. 20.

In spite of the war and industrialization, the frequency of sympathetic ophthalmia following perforating injuries was reduced from 2.90 percent in 1900 to 1918 to 1.72 percent in 1919 to 1935. This is to be attributed to improved prophylaxis, that is, insistence on enucleation of the injured eye in threatened sympathetic ophthalmia. Because of the large number of perforating ocular injuries during the war the diagnosis of threatened sympathetic ophthalmia becomes very important. To point out the difficulty of diagnosis Rabinowicz cites the fact that of 914 eyes enucleated in 1926 to 1934 with the diagnosis of sympathetic ophthalmia, only in 25 was the diagnosis confirmed microscopically. The author reviews the literature on the efforts to find assistance for the diagnosis in the blood mor-

phology, and gives a condensed report of his own studies on 120 patients with severe perforating ocular injuries and severe clinical symptoms of iridocyclitis, acute or chronic. Blood studies, where possible, were made on the day the injury was received, and every other day after that. The data confirm the published findings that monocytosis, when it occurs, does not appear before the eighth or ninth day. Of the 120 case histories 48 contain a histopathologic report; in 72 this was not available. Of eight cases, confirmed histologically as threatened sympathetic ophthalmia, in six there was a high monocytosis, in one a moderate monocytosis, and in one a slight lymphocytosis without monocytosis. The monocytosis found in the seven cases receded very slowly after enucleation. In two cases, one clinically severe and one moderately severe, in which the histologic diagnosis between infiltrating uveitis and endophthalmitis could not be made, there was moderate monocytosis, slowly receding after enucleation. The author believes that the blood morphology of these ten cases supports the already demonstrated relation between monocytosis and sympathetic ophthalmia. In 15 cases with histologically confirmed endophthalmitis, monocytosis was absent. In 17 cases of uveitis, histologically lacking the characteristics of sympathetic ophthalmia, there was high monocytosis in five cases, moderate in six, and none in six. The degree of monocytosis ran parallel with the severity of the clinical symptoms. Of the 72 clinical case histories without histologic data, in 68 there was complete correlation between the monocytosis and the severity of the clinical symptoms. The author believes that the blood picture is a very sensitive indi-

cator of infection, and that monocytosis develops prior to demonstrable histologic processes. The slow recession of the monocytosis after enucleation shows that the infection remains in the blood for some time, and explains the occurrence of sympathetic ophthalmia several weeks after enucleation of the injured eye. Zavalia, J. M., and Amado, C. F. **Bilateral iridocyclitis and band opacity of the cornea in Still's disease.** *Anales Argentinos de Oft.*, 1942, v. 3, Oct.-Nov.-Dec., p. 189.

Still's disease is a form of rheumatism or arthritis, resulting from a chronic infectious process caused by the streptococcus viridans. The portal of entry is the throat, teeth, or sinuses. The ailment occurs principally in children, although an adult form has been described. The case now reported is that of a boy of ten years in whom the disease had appeared at the age of one year, as small painless cysts of the wrist and knees, with progressive enlargement. The child was poorly developed and showed polyglandular swellings and marked deformities of the extremities. Each eye presented a transverse film of the cornea, scleral staphyloma, and chronic iridocyclitis. A blood culture showed a gram-positive streptococcus. The literature is reviewed and discussed. CRYSTALLINE LENS

Carleton, Alice. **Skin disease and cataract.** *Brit. Jour. Derm. and Syph.*, 1943, v. 55, April, p. 83.

The skin diseases in which juvenile cataract may occur are allergic eczema, poikiloderma, and scleroderma.

Cases of allergic eczema in association with cataract are briefly reviewed. In the discussion of the investigation of others, the author brings out the fact that in allergic eczema no specific allergen has ever been proved. A case of familial telangiectasia and cataract with myotonic dystrophy is described. These skin diseases are said to be genetically inherited, though the type of genetic inheritance is different in each.

Guyton, J. S., and Woods, A. C. Oral use of prophylactic sulfadiazine for cataract extractions. *Amer. Jour. Ophth.*, 1943, v. 26, Dec., pp. 1278-1282.

Neblett, H. C. Choroidal detachment following cataract extraction. *Southern Med. and Surg.*, 1943, v. 105, May, p. 225.

Choroidal detachment occurs in 4 percent of the cases after cataract extraction. That it is not observed more often is attributable to the fact that many surgeons do not examine the fundus in the first eight to ten days after the operation and the detachment becomes reattached within ten days without any visible evidence of its former presence. The detachment is produced by injury of the ligamentum pectinatum during the operation, allowing aqueous humor to filter into the space below the choroid. Or it may be caused by the rupture of a choroidal vessel.

Subjectively the patient will complain of a dull, heavy feeling in the eye. Objectively a hemorrhage in the anterior chamber may be found. The wound margins are swollen, the anterior chamber is shallow, the globe is soft to palpation. Ophthalmoscopic examination will reveal a smooth, round, nonfluctuating, brownish-gray mass protruding into the vitreous and arising from either the nasal or the temporal half of the fundus.

One case history is given. A 55-year-old man had been operated upon for cataract. The operation and the post-operative course were uneventful until the eighth day, when the detachment of the choroid was noted. The choroid became reattached after the twelfth day. A few scattered areas of pigmentation in the retina were noted at the

site of the previously detached choroid.

RETINA AND VITREOUS

Craik, K. J. W. Specifications for dark-adaptation tests. *Brit. Med. Jour.*, 1943, May 22, p. 632.

To use the dark-adaptation tests intelligently and to enable one to compare the findings of different observers, standardization is necessary. That is, agreement must be reached as to size of field, form or figure used in the test, quality of light, duration of exposure, retinal area to be tested and so on. Moreover, there is an equal need of calibration, or of exact measurement of the physical properties of the instrument, to enable one to produce an exact copy of the instrument.

R. Grunfeld.

Ebert, R. H. Angioid streaks and pseudoxanthoma elasticum. *Arch. Derm. and Syph.*, 1943, v. 48, July, pp. 75-82.

Ebert describes angioid streaks, ophthalmoscopically, as jagged, irregular streaks, in some cases radiating in spokelike fashion from the region of the discs, in others anastomosing and intersecting. Angioid streaks were associated with serious pathological alterations of the macula in 140 of 188 cases, as covered by one review. The differential diagnosis is discussed briefly by Ebert. Pseudoxanthoma elasticum is characterized by yellow plaques, occurring especially in the skin folds. It is symptomless. Pathologically, there is destruction of elastic fibers in the skin. The degenerated elastic fibers are rich in calcium.

The cause of each of these diseases is unknown, but both are rare, and they are too frequently associated for the experience to be coincidental. Ebert stresses the points of similarity, and cites statistics correlating the two conditions. The pathology of angioid streaks is uncertain, the evidence conflicting. Verhoeff found folds in Bruch's membrane and the choriocapillaris, but the remaining eye showed no angioid streaks; Law found a similar appearance of folds, but did so in an eye sectioned after being in fixatives several months. In Benedict's case, no retinal pathology was found. Bock and Hagedoorn observed cases showing in Bruch's membrane atrophic changes which by serial reconstruction resembled angioid streaks seen ophthalmoscopically. Apparently the two diseases are related instances of disease of the elastic tissue, but their exact nature has not yet been determined.

See editorial, this issue, page 189.

Riddell, W. J. B. **On testing dark adaptation.** Glasgow Med. Jour., 1943, v. 21, June, pp. 149-157.

The author describes his modification of the Birch-Hirschfeld adaptometer, so arranged that a relatively constant portion of the retina is tested, in an area where there is an approximately equal distribution of rods and cones. The paper is essentially a series of generalizations concerning the testing of dark adaptation. The author describes the wide range of light intensities covered, necessitating the logarithm unit for plotting the curves of dark adaptation. The varying sensitivity of rods and cones to light of different wave-lengths is discussed, as well as the variations in the cone-rod transition-time produced by varying the preliminary light-adaptation period. The paper stresses the importance of studying the entire curve of dark adaptation, rather than just the final rod-threshold, in correlating nutritional studies with organic disease such as hepatic cirrhosis. Benjamin Milder.

Wolff, Eugene. **Retinitis proliferans.** Trans. Ophth. Soc. United Kingdom, 1942, v. 62, pp. 115-122.

The author discusses the fate of the blood after a vitreous hemorrhage. He describes a microscopic specimen in which the fluid remained and tended to form a blood cyst. The membranous wall (retinitis proliferans) was traced over the internal limiting membrane of the retina. It suggested separated vitreous and contained blood elements. (3 illustrations, references.)

Beulah Cushman.

Yudkin, J., and Ferguson, A. **A critique of the Bishop Harman test for night vision.** Brit. Med. Jour., 1943, May 22, p. 632.

The authors critically analyze Harman's new apparatus for measuring night vision. The apparatus consists of groups of white discs mounted on a black background and illuminated by a standard candle five meters away. After 15 minutes of dark adaptation the subject is required to stand at such a distance that he is just able to distinguish the discs and count them. A shorter distance indicates poorer, a greater distance, better night vision.

The analysis reveals that the instrument is faulty in many respects on theoretical consideration. It proved also to be unsatisfactory on practical application. The dark adaptation of thirty subjects was examined with this apparatus and compared with the results obtained on the Haines instrument. The results obtained by the two instruments showed but little correlation. R. Grunfeld.

Yudkin, J., Robertson, G. W., and Yudkin, S. **Vitamin A and dark adaptation.** Lancet, 1943, v. 245, July, pp. 10-13.

Using an instrument modified from the Crookes adaptometer, the authors measured the complete course of dark adaptation in four hundred subjects. By their technique, after light-adapting the subject, the retinal threshold was measured repeatedly over a period of forty minutes. Their graphs show, typically, an initial rapid adaptation (the "cone threshold") followed by a slower adaptation (the "rod threshold"). The authors stress the importance of evaluating dark adaptation in terms of the entire function—that is, the cone threshold, the rod threshold, the transition time between these two phases, and the final rod-threshold level. They believe that the adaptometers which measure the visual threshold at one

particular time are misleading, and in many cases erroneous. If one single criterion is to be selected, it should be the final rod-threshold.

The authors made an intensive study of the influence of altered vitamin-A intake (marked increases and decreases) on the dark adaptation of a series of normal individuals, and found that alterations in any of the phases of the dark adaptation curve were possible, but the most constant changes were in the final rod-threshold—the condition approaching complete dark-adaptation.

OPTIC NERVE AND TOXIC AMBLYOPIAS

Doggart, J. H. On diagnosing papilledema. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 141-144.

The author mentions the following objective signs of papilledema as of value in forming an opinion as to the significance of swelling of the disc during the early stages: (1) slight parallax movement, (2) the impression of a slight forward thrust of the disc (one diopter or more), (3) turgidity of veins, (4) alteration in the light reflex of vessels crossing the edges of the disc, (5) hemorrhages, (6) partial or total obliteration of the physiologic cup, (7) enlargement of the blind-spot, (8) blurring of the disc edges.

Leinfelder, P. J. Choked discs and low intrathecal pressure occurring in brain tumor. *Amer. Jour. Ophth.*, 1943, v. 26, Dec., pp. 1294-1298; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41. (One table, references.)

Nceme, Humphrey. Congenital hole in the optic disc, with a scotoma.

Trans. Ophth. Soc. United Kingdom, 1942, v. 62, p. 137.

The author reports the case of a patient who had a hole in the optic disc. The lower half of the visual field was lost up to the area of fixation. The tension was normal and there was no pathologic cupping of the disc. One other patient with a hole in the disc had no visual-field changes.

Beulah Cushman.

Voss, O. Neurolysis of the optic nerve. *Zentralblatt für Chirurgie*, 1942, v. 69, April, pp. 595-601.

A woman of 47 years sustained a severe fracture of the base of the skull in an automobile accident. The right eye had to be enucleated. After convalescence was completed, gradual deterioration of the visual acuity of the remaining eye was noticed. There was temporal hemianopsia, but central vision was fairly good. Other neurological findings were normal.

Operation was performed under local anesthesia after preliminary luminal. Dandy's technique was used, the skin flap being reflected forward and the bone flap toward the temporal region. The opening of the bone flap was attended by considerable difficulty, the dura being quite generally adherent to the bone. The surface of the brain showed a marked arachnoiditis, particularly in the frontal pole and along the superior sagittal sinus. After various anatomic preliminaries, there was found an unmistakable arachnoiditis of the cisterna of the chiasm. The left optic nerve was wrapped in scar tissue of appreciable thickness, contraction of which was unmistakably causing pressure upon the nerve. There was apparently no pathologic condition of the bone in the region of the optic foramen, particularly in the form of an exostosis,

and the nerve appeared normal outside of the scarred area. All the adhesions were separated with a hook, leaving the nerve entirely free. The scar tissue which had surrounded the nerve was split and partly removed, as also were the arachnoidal adhesions in the vicinity. There were similar conditions on the right side, but no resection was undertaken here, because of the absence of the right eye. Several weeks later the patient showed no further advance in visual disturbance. The visual field had undergone no further change. The patient returned to her work as librarian.

In the second patient, a soldier who had been injured by a grenade from which several splinters were lodged in the anterior cranial fossa, the technique of operation was similar to that in the first patient. In attempting to approach the chiasm, the anterior pole and the floor of the right frontal lobe were found extensively adherent to the dura. Parts of the frontal pole were resected, the frontal lobe freed from the floor of the anterior fossa, and the right optic nerve gradually exposed. There was a good deal of scar formation, the optic nerve itself being surrounded by a circular callous. The latter was split in the direction of the nerve fibers. It was then found that peripherally from the chiasm the right nerve had been torn half way through on its medial side by a rather small irregular grenade splinter which was still in place. The circular mass of scar tissue was excised as accurately as possible, and arachnoidal adhesions in the angle of the chiasm were also divided. The left nerve was macroscopically normal. Postoperative convalescence was complicated by necessity for repeated puncture to get rid of accumulations of fluid beneath the skin flaps, and also by a mild meningeal infection.

But the visual disturbances went no further and the patient's general condition was considerably improved, with disappearance of severe headache which had existed before the operation.

The author suggests that the optic nerve has a materially greater capacity for regeneration than an ordinary spinal nerve. (3 illustrations.)

VISUAL TRACTS AND CENTERS

Goldstein, Kurt. Some remarks on Russel Brain's article concerning visual object-agnosia. *Jour. Nerv. and Ment. Dis.*, 1943, v. 98, Aug., p. 148.

The author disputes Brain's assumption that the disturbance of recognition in the case of visual agnosia, which the author has described, was due to impairment of perception and specifically to a defect of the visual field, for the visual field in this case was almost normal. The patient's defect can be understood only as an impairment in the perceptual sphere concerning the degree of form perception, and it warrants a special name, that of visual agnosia.

R. Grunfeld.

Mahoney, V. P., and Linhart, W. O. Amblyopia in hysteria. *War Medicine*, 1943, v. 3, May, p. 503.

The authors report 13 cases of hysterical amblyopia. Laboratory work-up psychobiologic studies and ocular examinations including form and red fields, were made on these patients. Concentrically contracted fields and characteristic disturbances of personality were found. Acute, chronic, and mixed types were noted. The authors remind us that hysterical amblyopia occurs in psychobiologically underdeveloped persons and is akin to an acute

hysterical reaction. These cases should be referred to a psychiatrist.

EYEBALL AND ORBIT

Harley, R. D. *Exophthalmos in the newborn*. *Amer. Jour. Ophth.*, 1943, v. 26, Dec., pp. 1314-1315.

Reese, A. B., and Khorazo, D. *Endophthalmitis due to B. subtilis following injury*. *Amer. Jour. Ophth.*, 1943, v. 26, Dec., pp. 1251-1253. (References.)

Sudakevich, D. I. *Orbital prosthesis for the sequelae of war injuries*. *Viestnik Oft.*, 1943, v. 23, pt. 1, p. 25. (See Section 16, Injuries.)

Sunder-Plassmann, P. *Malignant exophthalmos*. *Zentralblatt für Chirurgie*, 1942, v. 69, Jan. 17, pp. 88-92.

The author's introduction includes mention of a clinical case in which perforation of the corneas rendered bilateral enucleation necessary. The patient whose case report occupies most of the article was a woman of 55 years who, after an accident in which she was in fear of death, developed malignant exophthalmos which failed to yield to prolonged treatment with various forms of medication, as well as by excision of conjunctiva and the use of X rays to the hypophysis. The eye surgeon stated that both eyes were in immediate danger of spontaneous perforation.

Radical operation was therefore undertaken in accordance with Naffziger's technique. The patient was trephined on each side, with formation of bone flaps carrying the temporal muscles. The ventricles were punctured, the basal dura pushed aside, and the

frontal lobes drawn backward. Both orbits were completely decompressed, and the orbital fascia was opened and the individual eye muscles exposed, with avoidance of the frontal branch of the trigeminal nerve. The levator palpebrae, the superior rectus, the internal rectus, and the lateral rectus were found tremendously enlarged, to about the thickness of a thumb. They were firmly adherent to one another, and had to be separated with a fine scalpel. The roof of the optic-nerve canal on each side was decompressed almost as far back as the hypophysis. There was severe edema of the optic nerve on each side, but no change in the orbital fat. At the close of the operation the dura and frontal lobe rested directly on the eyeballs. The patient made a fine recovery, although in the first two days she had a periphlebitis of the leg. There was no longer necessity for the morphine under which it had been necessary to keep the patient before the operation. The exophthalmos rapidly receded. Three months after the operation there was perfect closure of the eyes, and the corneal ulcers had long since healed. The eye clinic reported "normal visual acuity" and good motility of the eyeballs. A year after the operation the patient had gained 35 pounds, and was carrying on all her activities upon a farm. The author states this to be, so far as he knows, the first case of extreme malignant exophthalmos to be operated upon bilaterally in Germany with successful result. (5 illustrations.) W. H. Crisp.

Tucker, John. *Hand-Schüller-Christian disease (idiopathic xanthomatosis)*. *Cleveland Clinic Quarterly*, 1943, v. 10, July, p. 55.

Hand-Schüller-Christian disease occurs most frequently in children under

two years of age. The principal manifestations of the syndrome are osseous xanthoma (producing defects in the membranous bones of the skull), exophthalmos, and diabetes insipidus.

A case of Hand-Schüller-Christian syndrome is reported. X-ray treatment caused extensive healing of the bony defects of the skull. The use of pitresin tannate simplified the treatment of the diabetes insipidus. (6 illustrations.)

EYELIDS AND LACRIMAL APPARATUS

Costa, O. G. *Microsporon* infection of the palpebral and ciliary regions. *Arch. Derm. and Syph.*, 1943, v. 48, July, pp. 65-69.

Costa reports a case of tinea due to *Microsporon felineum*, in a negro boy. The lesions occurred on the scalp, ears, eyelids, and lashes, producing on the latter a patchy pseudoalopecia and some trichiasis. The diagnosis was supported by culture, mycologic examination and trichophytin test. The infection is usually transmitted by cats and dogs. (3 photographs.)

Benjamin Milder.

Seemen, Hans. A rare disfigurement from scalping—result of new type of restorative operation. *Zentralblatt für Chirurgie*, 1942, v. 69, Aug., pp. 1280-1287.

The hair of a 15-year-old girl was caught in a drive belt, with complete

scalping accompanied by shock, and followed by fever, purulent secretions from the wound, and bad general condition. There was complete loss of the hairy scalp with the exception of slight remains just behind the attachments of the auricles. The right external ear had also been torn off and the defect scarred. Except over the root of the nose, the whole skin of the frontal area had been destroyed, including eyebrows and upper lids, with secondary bilateral ectropion. The outer halves of the lower lids were drawn upward, so that the palpebral fissure on each side was strikingly oblique. In normal position of the head, the lower half of the eyeball was covered by the lower lid, the upper margin of the lower lid bisecting the iris and pupil. The ectropion of the upper lids was so great that the eyelashes were turned directly backward. The eyelids could not be completely closed. The surgical procedures included steps for replacement of the scarred frontal skin with sound skin and reconstruction of the eyebrows. The transplanted skin was obtained from the side of the neck and the upper part of the chest. For the eyebrows, advantage was taken of the small remains of the hairy scalp, with special care to have the direction of the hair run from medial to lateral. Complete restoration of lid function was obtained, and the primarily existing "mongolian" facies was fully overcome. (14 illustrations.)

NEWS ITEMS

Edited by DR. DONALD J. LYLE
904 Carew Tower, Cincinnati

News items should reach the editor by the twelfth of the month

DEATHS

Dr. Ned A. Balding, Lincoln, Illinois, died October 6, 1943, aged 57 years.

Dr. Thomas V. Connolly, Paterson, New Jersey, died October 21, 1943, aged 53 years.

Dr. Vance M. Cox, Bristol, Virginia, died October 15, 1943, aged 63 years.

Dr. Zenas H. Ellis, New York, New York, died October 20, 1943, aged 48 years.

Dr. George F. Fiske, Chicago, Illinois, died October 18, 1943, aged 83 years.

Dr. Stephen A. Hemmi, Chicago, Illinois, died October 27, 1943, aged 85 years.

Dr. George F. Scheib, Champaign, Illinois, died November 2, 1943, aged 76 years.

Dr. Oscar O. Larsen, Detroit Lakes, Minnesota, died November 7, 1943, aged 66 years.

Dr. Douglas A. Payne, Chicago, Illinois, died November 24, 1943, aged 86 years.

MISCELLANEOUS

Dr. William H. Crisp, Consulting Editor and Head of the Abstract Department of the American Journal of Ophthalmology, is anxious to learn whether any ophthalmologist in this country is familiar with the Turkish language. The first issue of a new Turkish eye journal has just been received. Please communicate with Dr. Crisp, 530 Metropolitan Building, Denver, Colorado.

The executive office of the American Board of Ophthalmology has been moved to P.O. Box 1940, Portland 2, Maine. Officers for 1944 are the following: Dr. John Green, Saint Louis, chairman; Dr. Frederick C. Cordes, San Francisco, vice-chairman; Dr. S. Judd Beach, Portland, secretary-treasurer; and Dr. Theodore L. Terry, Boston, assistant secretary. The 1944 examinations will be held in New York, on June 3d and 4th; and in Chicago, on October 5th to 7th.

Announcement is made that the Directory of Medical Specialists is now to be published by the A. N. Marquis Company of Chicago, publishers of "Who's who in America." Previous editions have been published for the Advisory Board for Medical Specialties by the Columbia University Press of New York City.

It is planned not to issue the next edition before 1945, on account of the war, but the

A. N. Marquis Company will publish a supplemental list of all those who have been certified by the American Boards since the last (1942) edition of the Directory, totaling about 3,600. This is to be distributed at cost, and monthly or bimonthly bulletins listing successful candidates for certification at examinations during the additional interim before the next edition, are to be issued as a subscribers' service.

Dr. Paul Titus (Pittsburgh) of the American Board of Obstetrics and Gynecology will continue as the Directing Editor, and Dr. J. Stewart Rodman (Philadelphia) of the American Board of Surgery continues as Associate Editor. The Editorial Board will be composed, as before, of the secretaries of the 15 American Boards.

Communications should be addressed to the Directing Editor, Directory of Medical Specialists, 919 North Michigan Avenue, Chicago 11, Illinois.

SOCIETIES

The Washington, D.C., Ophthalmological Society held its regular meeting on January 10th. The guest speaker was Dr. Maynard C. Wheeler, New York City, who spoke on "Surgical treatment of vertical deviations." The following cases were presented: "Melanoma of the choroid" by Dr. Sterling Bockoven, "Parinaud's oculoglandular syndrome" by Dr. Frank D. Costenbader, and "An unusual case of hyalitis" by Dr. C. Robert Naples.

The Research Study Club of Los Angeles held its thirteenth annual postgraduate clinical conference in ophthalmology and otolaryngology January 17th to the 29th. Among the guest speakers were Dr. James Watson White of New York and Dr. Georgiana M. Dvorak-Theobald of Oak Park, Illinois.

A meeting of the Association for Research in Ophthalmology will be held on Tuesday, June 13, 1944, at the Hotel Sherman, Chicago. Applications for places on the program are being received and all communications should be mailed to the secretary, Major Brittain Payne, School of Aviation Medicine, Randolph Field, Texas.

PERSONALS

Dr. Erich Pressburger announces the removal of his offices to Suite 1436, 450 Sutter Building, San Francisco 8, California.

PERFECTED Plastic ARTIFICIAL EYES

NOTE: No stock eyes are available . . . all plastic eyes are molded and made to order to meet individual requirements.

Eye physicians will find definite benefits in the new perfected plastic artificial eyes:

NON-SHATTERABLE CONSTRUCTION saves the wearer the inconvenience, embarrassment and expense of accidental breakage. Plastic eyes do not discolor, become brittle, roughen, crack, or explode.

ANATOMICAL SHAPES ARE POSSIBLE. Impression molds of the socket are made, affording accuracy of detail to correct faulty conditions. Especially successful in cases of trauma due to chemical burns, gas explosion, causes incident to war, shrunken sockets, deformed or shrunken eyelids.

LIFELIKE APPEARANCE. Due to special characteristics of the acrylic compound, plastic eyes absorb more light and reflect less than glass eyes. Sclera and iris have a softer and more lifelike appearance. Cosmetic effects not obtainable with glass eyes are achieved.

GREATER COMFORT is assured because of more accurate fitting and the possibility of adapting plastics through molding of delicate tissue.

NOT CHEMICALLY AFFECTED. The acrylic materials of which plastic eyes are made absorb much less water than glass and are not affected by chemical reaction of the eye socket secretions.

SERVICE TO PHYSICIANS

Eye physicians are invited to contact us regarding patients for whom plastic eyes offer apparent advantages due to special conditions.

Our pamphlet of instructions for ordering Gougelman Perfected Plastic Eyes gratis on request.

PIGMENT FRECKLES OF THE IRIS (BENIGN MELANOMAS): THEIR SIGNIFICANCE IN RELATION TO MALIGNANT MELANOMA OF THE UVEA*

ALGERNON B. REESE, M.D.
New York

The presence of freckles on the anterior surface of the iris is common. Out of 300 adult patients with supposedly normal eyes, they were noted on one or both irides in 145, or 48 percent. In 93, or 31 percent of these, the freckles were on both irides (about equal in 82, greater on one iris than on the other in 11) and unilateral in 52 or 17 percent. These statistics are based on adult eyes as these pigment freckles do not appear before the age of 6 to 8 years and rarely before 12 years. This is in keeping with the occurrence of pigmented nevi of the skin, which also appear at this age. Although the term "freckles" seems convenient to employ clinically, these iris lesions really represent multiple benign melanomas.

The author has noted the more frequent occurrence of benign melanomas of the iris in the microscopic sections of eyes harboring malignant melanomas of the uveal tract. These have been observed in 13 eyes in which the malignant melanoma was present in the choroid and in 6 eyes in which it was present in the iris or ciliary body.

The histologic difference between the melanomas of the iris seen in normal

eyes and those seen in eyes with malignant melanoma seems to be one of degree. In the case of the normal eye the lesion is a localized accumulation of densely pigmented melanoblasts only a few cells thick along the anterior surface of the iris. In fact, the lesion could be characterized as merely a localized thickening of the anterior limiting layer of the iris which, in some instances, has the appearance of being proliferated endothelium. Such a lesion may sometimes contain little or no pigment.

The melanomas of the iris in eyes with malignant melanoma are more extensive lesions (fig. 1 a, b, c, d). They tend to be slightly more elevated above the iris surface and to extend deeper into the iris stroma. Sometimes they actually arise in the stroma (fig. 1 b) and may even cause an increase in the thickness of the iris. In one instance an ectropion uvea was produced (fig. 1 c). The type cell is the melanoblast, varying in shape from plump polygonal to long, branching, pigmented cells. When the cells spread through the entire thickness of the iris, they seem to have a predilection to abut on the dilator-muscle layer in a manner that steel fragments display toward a magnet. The cells are more matured than those of the malignant melanoma but sometimes less matured than those comprising the physiologic melanomas of the

* From the Institute of Ophthalmology of the Presbyterian Hospital. Read at the seventy-ninth annual meeting of the American Ophthalmological Society, Hot Springs, Virginia, June 11, 1943.

1 a, A benign melanoma of the iris extending through the entire thickness of the stroma.

1 b, A benign melanoma of the iris arising in the iris stroma.

1 c, A benign melanoma of the iris occupying the entire pupillary area, increasing the thickness of the stroma and causing an ectropion of the uvea (from the collection of Dr. Georgiana Theobald).

1 d, A benign melanoma of the iris occupying the pupillary area. The cells composing this resemble more closely the cells of the malignant melanoma of the choroid than in cases "a," "b," and "c."

Fig. 1 (Reese). Four illustrations of benign melanoma of the iris in eyes with malignant melanoma of the choroid.

Fig. 2 (Reese). Four illustrations of benign melanomas of the iris in eyes with normal irides and not harboring a malignant melanoma of the choroid.

iris. In one instance the cells of the iris lesion were of about the same maturity as those of the malignant melanoma in the choroid (fig. 1 d). No endothelium has been identified over their surface. There seems to be no predilection for any particular area of the iris. There is no tendency to encapsulation.

Sections of 100 eyes not having a malignant melanoma and with normal irides were examined and iris melanomas

there was a malignant melanoma of the choroid and not present on the iris of the fellow eye. In the first case (fig. 3, plate 2), the choroidal tumor located in the macular region was flat and nonpigmented, and a differential diagnosis from other conditions was necessary. In the second case (seen through the courtesy of Dr. R. C. Castroviejo), there was a retinal detachment over the choroidal tumor and the diagnosis was not clear.

Fig. 4 b (Reese). Microscopic section through the large freckle on the iris shown in figure 4 a.

were noted in 26, or 26 percent. Four of these were extensive enough to be comparable to those seen in eyes with malignant melanoma (fig. 2). It is interesting to note that the patients in three of these four cases had an extraocular tumor but not a malignant melanoma; however, most of the normal eyes that the author has available for microscopic study are ones that have been enucleated because of a neoplasm of the adnexa.

Because of the frequency with which these melanomas of the iris have been observed in the microscopic sections of eyes harboring malignant melanomas of the choroid, the author made an effort to identify them clinically. In three instances pigment freckles have been noted as present on the iris of the eye in which

(figs. 4 a, plate 1, and 4 b). The third case (seen through the courtesy of Dr. W. A. Boyce) was one in which the lesion occupied the macular region, was flat, and had no appreciable pigment content (fig. 5). In each of these three cases freckles were present on the iris of the involved eye and not present on the iris of the fellow eye. This finding was considered significant and thought to lend substantiating evidence to the correct diagnosis. No difference was noted clinically between the appearance of these freckles and those seen in normal eyes, although the cases were not studied with this particular object in view. The fact that freckles were present on one iris and not present on the other was considered most significant. What their appearance

would have to be in order to be of significance in cases with bilateral physiologic freckles, or in cases with freckles normally more marked on one iris than on the other, is not known. From the microscopic picture there should be some clinical differences, if only for the reason that the one is more extensive than the other. A sufficient number of cases have not been seen clinically to allow any statement as to possible differences to be made. Even the most extensive ones seen microscopically were not noted clinically.

These melanomas of the iris are considered manifestations of multiple origin of the tumor. They are composed almost invariably of more matured tumor cells than is the main lesion, or of completely matured cells, and are therefore benign with little or no power of active growth. Similar instances of multiple origin of melanomas are seen elsewhere in the uveal tract. In the cases studied here the main lesion is in the choroid and the lesser lesion in the iris, but it may be elsewhere in the choroid or in the ciliary body. The main lesion, moreover, may be in the ciliary body and the lesser one in the iris or choroid, or the main lesion may be in the iris and the lesser lesion also in the iris or in the choroid.

The question of whether or not these iris melanomas are implantation growths must be considered. Such manifestations of cancer are well known. In cases of retinoblastoma implantation growths are frequently seen, and the anterior surface of the iris is not an uncommon site. Such manifestations in cases of malignant melanoma of the uvea occur but are extremely rare. They are more frequently seen when the primary growth occurs in the ciliary body and iris. In such cases the disseminated tumor cells have easy access to the anterior chamber where they may implant themselves and grow along the iris and in the filtration angle. Such

implantation growths around the circumference of the angle and iris are responsible for the ring character of some malignant melanomas (fig. 6 a, plate 1, and fig. 6 b). The melanomas of the iris discussed in this paper do not seem to be implantation growths. The cells composing them are not comparable usually

Fig. 5 (Reese). Freckles on the iris of an eye with a malignant melanoma of the choroid. There were no freckles on the iris of the fellow eye.

to the cells of the primary lesion. In only one instance were the cells of the iris lesion of about the same maturity as those of the choroidal lesion (fig. 1 d). Furthermore, the melanomas studied here tended to involve the entire iris, whereas implantation growths occur on the surface. The writer has never seen an implantation lesion of the iris from a malignant melanoma of the choroid.

In cases of malignant melanoma of the skin there may occur daughter areas or freckles around the primary focus, and these are generally said to be extensions along the lymphatics. The comparable iris lesions, however, do not seem to represent extension along the lymphatics from the primary focus but are usually multiple origins. They may very exceptionally represent implantation and, even more rarely, they may represent direct extensions by continuity along the iris surface from the primary lesion.

The question of whether the iris lesions are metastatic foci carried through the blood stream from the choroidal lesion hardly warrants consideration. The author has seen one instance of a metastasis by way of the blood stream from the primary site of the malignant melanoma in the uvea to a site elsewhere in the eye. In this case the primary lesion was

that malignant melanomas of the uvea are neurogenic in origin—it can be argued that the multiple origin of melanomas of the uvea all emanate from some common neurotrophic influence.

This is borne out in a case reported by Goldstein and Wexler.² Their patient had multiple neurofibromata of the skin, multiple pigment lesions of the skin, fi-

Fig. 6 b (Reese). Microscopic section of above case (line in figure 6 a indicates site of section) showing one iris growth from implantation and one from direct extension along the anterior surface of the iris from lesion in the ciliary body. Other sections showed iris lesions which were instances of multiple origin.

in the choroid and the small metastatic focus was in the vascular layer of the ciliary body on the opposite side.

The nature of these multiple origins. Benign pigment lesions in the form of melanosis (café-au-lait spots) and nevi occur in the skin and tissue adjacent and distal to such neurogenic tumors as neurofibromatosis. Also, the common skin nevus is thought to be neurogenic. Thus, there seems to be some relationship between pigment production and nerve-tissue function or aberration. Assuming therefore that Georgiana Dvorak-Theobald's¹ contention is correct—namely,

bro sarcoma of the back, and multiple melanomas of both irides. There were also stigmata of acromegaly and other features indicating tumor involvement of the central nervous system. This case illustrates the multiple origin of melanomas, associated with multiple neurogenic tumors, manifesting one malignant focus as well as innumerable benign foci all over the body, including the irides.

In cases of neurofibromatosis sometimes the multiple manifestations of the disease, including the pigment lesion, tend to follow the distribution of a nerve. In cases of malignant melanoma of the uvea the iris melanomas do not seem neces-

sarily to appear in the same quadrant or sector of the eye, indicating the same nerve distribution.

Another conception of the multiple manifestation of melanomas is that some cancerigenic agent acts on the whole uveal tract causing a malignant melanoma at one site and more or less benign melanomas at other sites. There are similar occurrences elsewhere in the body. Among these can be mentioned cancerous lesions that occur simultaneously throughout the gastro-intestinal tract (mouth, esophagus, stomach, and rectum). Also, there may be papillomatous lesions over a wide area of the gastro-intestinal tract; epitheliomatous lesions over the face with simultaneous and widespread multiple precancerous lesions, in which instance the cancerigenic agent is thought to be the actinic effect of the sun's rays; in the mouth there may occur multiple carcinomas and precancerous lesions that are thought by some to have a common cause in syphilis, in avitaminosis, or perhaps in the use of tobacco. Lymphosarcoma may manifest itself for a long time at one site as a localized tumor and later show multiple origins elsewhere. Both breasts and both ovaries may be simultaneously affected with cancer or precancerous lesions. The multiple origin of a retinoblastoma not only in the one eye but in both eyes is well known, and the primary site is malignant, whereas the secondary sites may be relatively benign. In all of these instances there seems to be some common agent or factor at work producing tumor changes of varying degrees over a wide area of a particular system. Verhoeff has suggested that some substance may emanate from the main lesion causing a localized proliferation of melanoblasts elsewhere in the uvea.³

Two instances in which the main lesion was in the iris or ciliary body and

the lesser lesion in the iris serve to indicate certain characteristics. In the one case there was a malignant melanoma of the iris with four pigment freckles on the iris at the side opposite to the tumor. There were two small freckles on the fellow iris. The tumor was excised locally by Dr. John M. Wheeler and the microscopic diagnosis was malignant melanoma. Seven years have now passed during which time there has been no recurrence of the tumor nor have the pigment freckles, which were not excised, grown. This case bears out the fact that the freckles are composed of mature cells with little or no power of active growth. In the other case, a flat melanoma, measuring 1 by 3 mm., was noted in the periphery of the iris during a routine examination (fig. 7 a, plate 2). Presumably the lesion had been present for an indefinite length of time. Observations were made regularly every three to six months. Gonioscopic examinations, drawings, and photographs were made at varying intervals. No change was detected during the period of observation until after the passage of eight years, when it was noted with the gonioscope that the anterior chamber angle could no longer be seen over the site of the tumor, indicating an increase in elevation. At the same time two freckles appeared on the iris above the main lesion. These had appeared in six months' time. After two-and-one-half months more a third freckle appeared above the other two. The main lesion still measured 1 by 3 mm. The eye was enucleated. Microscopically, the tumor proved to be a malignant melanoma arising apparently from the site of a benign melanoma (fig. 7 b). The pigment freckles were composed of more matured cells than was the main lesion and seemed to represent multiple origins of the tumor (fig. 7 c). They appeared coincidentally with the active growth of the main lesion,

Fig. 7 b (Reese). Microscopic section of iris melanoma shown in figure 7 a. This is a malignant melanoma apparently arising from the site of a benign melanoma.

Fig. 7 c. Microscopic section through the freckle shown in figure 7 a.

Fig. 8 (Reese). A diffuse malignant melanoma of the choroid which has extended out of the globe at the posterior pole. There is a detachment of the retina and secondary glaucoma.

which fact suggests that their appearance on the iris indicates active or malignant growth of the main lesion.

Relation of the iris melanomas to malignant melanoma of the uvea in gen-

eral. A malignant melanoma of the uveal tract is usually a localized tumor mass; occasionally, however, it manifests itself as a diffuse lesion involving sometimes the entire uvea (fig. 8). It may also appear as a diffuse lesion involving only a

Fig. 9 b (Reese). Microscopic section of above case (line in figure 9 a indicates site of section).

portion of the uvea, such as the iris (fig. 9 a, plate 2, and fig. 9 b) and/or the ciliary body (fig. 6 b). The malignant melanoma occurring as a localized mass in the uvea, with benign melanomas elsewhere, seems to be the bridge or link between the usual type of localized malignant melanoma of the uvea and the diffuse malignant melanoma. The cancerigenic factor has its effect at a localized site alone (usual localized malignant melanoma of the uvea) and to a lesser degree elsewhere (malignant melanoma at one site and benign melanoma elsewhere), or in a diffuse manner over the uvea (diffuse malignant melanoma of uvea or iris and ciliary body, or ring melanoma). The ring nature of a melanoma seems to be due in part to multiple diffuse origins as well as to implantation growths which logically occur around the filtration angle where disseminated tumor cells in the anterior chamber would tend

to gather. An important difference between a localized malignant melanoma of the uvea with benign melanomas elsewhere, and a diffuse and ring type of melanoma, is that the cancerigenic agent had a malignant effect at one site and a benign effect elsewhere in the one case and a diffuse, multiple malignant effect in the other cases.

CONCLUSIONS

A malignant melanoma of the uvea may be accompanied by a single or by multiple benign melanomas. Such instances represent multiple origin of the tumor, and the iris is a common site for the benign feature. When the iris lesion is seen clinically it is a diagnostic aid.

I wish to express my appreciation of the assistance rendered by Miss Lilly Kneiske.

SOLAR KERATOCONJUNCTIVITIS ASSOCIATED WITH AMBLYOPIA*†

REPORT OF TWO CASES

CONRAD BERENS, M.D.

New York

AND

PAUL T. McALPINE, CAPT. (MC), A.U.S.

Summit, New Jersey

Although no reports have been found in a study of the literature concerning amblyopia associated with the exposure of the eyes to ultraviolet rays, the widespread use of ultraviolet-producing lamps makes it likely that more cases similar to those presented in this paper will be reported or have occurred.

Two brothers, J. H., and G. H., white, 23 and 26 years of age, respectively, purchased a small, inexpensive carbon-arc lamp which consisted of a reflector with two exposed carbons. With this lamp, they gave themselves three 15-minute periods of irradiation within 48 hours. The exposure was made with the patients seated about three feet in front of the lamp, facing it, with no protection for the eyes and with the eyes kept open most of the time.

Approximately six hours after the last exposure the patients complained of severe ocular pain, photophobia, and lacrimation. On January 25, 1939, six hours after the onset of the symptoms they were admitted to the New York Eye and Ear Infirmary. Examination of each patient showed slight redness and swelling of the eyelids with marked blepharospasm. There was profuse lacrimation and moderate diffuse redness of the conjunctiva. When the corneas were stained with fluorescein, a diffuse stippling re-

sembling superficial punctate keratitis was seen. Because of the intense photophobia and blepharospasm accurate determination of the visual acuity and satisfactory examination of the fundi could not be made.

Symptomatic treatment was administered, consisting of mydriasis with 2-percent homatropine, cold bathing, the use of boric-acid ointment, analgesics, and sedatives.

The following day the patients were comfortable but vision was reduced to the perception of hand movements. Examination of the fundi, while not entirely satisfactory, seemed to show no abnormality.

Two days after admission the pain, photophobia, lacrimation, and redness had completely disappeared, but the vision remained unimproved. A thorough fundus examination revealed nothing abnormal.

Peripheral visual fields were studied on the third day, January 28, 1939, using the Ferree-Rand perimeter. The vision of the first patient, J. H., was perception of hand movements. In testing his visual fields a 15-mm. white test object was used at 330 mm. with 7.5 foot-candles of illumination. The fields were reduced to a small temporal crescent in each eye (fig. 1.) On January 30th, the vision was the same and the fields unchanged. A light field was performed later on the same day, at which time vision had improved to the counting of fingers at 24 inches in each eye. The light field showed

*From the New York Eye and Ear Infirmary.

†Aided by a grant from the Ophthalmological Foundation, Inc.

a bitemporal hemianopsia (fig. 2).

On February 1, 1939, the vision was the same but the temporal crescents were larger when the visual fields were tested. The following day, vision had improved slightly and the visual fields had changed, the nasal field was beginning to be restored but there was still a large central scotoma (fig. 3). On the following day, February 3d, there was a return of vision (as tested with the pinhole) to R 20/100 and L 20/40 and the central and peripheral visual fields, as tested with the 3/330 white test object, were almost normal. On February 6th, the visual fields showed in the right eye, a relative central scotoma for blue of 4 degrees, with a marked contraction of the inferior temporal quadrant as tested with 1/750 white test object. The left eye showed a relative central scotoma for blue about 4 degrees and for green about 2 degrees with approximately normal fields (fig. 4).

Homatropine refraction was performed, and when the patient was last seen on February 21, 1939, the vision was: R.E. $-4.00D.$ sph. $\approx -0.50D.$ cyl. ax. $30^\circ = 20/20-2$; L.E. $-2.00D.$ sph. $= 20/30$; 300 mm. print could be read at 140 mm. with each eye.

The course of the second patient, G. H., and the visual-field changes paralleled those of his brother. On January 28 and January 30, 1939, the vision was reduced to perception of hand movements in each eye. The visual fields as tested with the 25-mm. white test object at 330 mm. showed only a temporal crescent to be present (fig. 5). The light fields taken on January 30, 1939, did not show the hemianopsia that was seen in the first patient but were more uniformly contracted. On February 1, 1939, vision was: R.E., the ability to count fingers at 8 inches; L.E., finger counting at 14 inches. The visual fields were quite uniformly and markedly contracted, but no central

scotoma was demonstrated with the size test object used (fig. 6). By February 3, 1939, the vision (as tested with the pinhole) was: R.E. 20/40-1 and L.E. 25/30; the central and peripheral fields, as tested with the 3/330 white test object, were almost normal. On February 6, 1939, the visual field showed an absolute central scotoma for green of 2 degrees in each eye and normal central fields as tested with the 1/750 white test object.

With the correction which the patient was wearing (R.E. $-2.25D.$ sph. $\approx -0.25D.$ cyl. ax. 90° , and L.E. $-2.25D.$ sph. $\approx -0.50D.$ cyl. ax. 90°), his vision was 20/20 in each eye.

In both patients, the general physical and complete neurologic examinations (except for the visual findings) showed no abnormalities. Roentgenograms of the accessory nasal sinuses and sella turcica were normal. Complete blood counts and urinalyses were within normal limits. The blood Wassermann reactions were negative.

Repeated fundus examinations, including one made with the binocular ophthalmoscope and with the red-free filter, showed nothing abnormal.

COMMENT

The carbon-arc lamp is a convenient source of ultraviolet radiation. This radiation depends upon the amount of current used and the type of carbon that is employed. The neutral (pure carbon) core carbon arc is rarely used. Carbons impregnated with "rare earth" oxides—yttrium and the like,¹ iron oxide, calcium oxide, and strontium—are used. In order to obtain sufficient radiation for effective therapeutics a lamp must be one of high amperage. In general, carbon-arc lamps give off radiations from 2,200 to 40,000 A.U.

For ordinary purposes it may be con-

sidered that radiations about 15,000 A.U. (infrared rays) are totally absorbed by the media of the eye. Below this the amount reaching the retina gradually increases, according to Hartridge and Hall, until at 9,000 A.U., 90 percent is transmitted. The high transmissibility is maintained through the visible spectrum, until 4,000 A.U. is reached, when absorption by the lens begins again. Absorption by the lens increases until at 3,200 A.U. transmission to the retina ceases.² It has been estimated that approximately 3 percent of the total heat incident upon the eye reaches the retina.

Another factor that determines the amount of incident energy to reach the retina at any one point is that of concentration. This depends upon the size of the source of energy and upon the dioptric system of the eye; the smaller and more concentrated the source the greater the concentration of energy at the retina in any one spot. Thus, retinal damage may occur without injury to the structures of the eye anterior to it.

The retina may be affected by light in one of three ways: There may be the sensation of vision; there may be a thermal effect; and there may be a chemical or abiotic effect. It may readily be seen how the first two take place, but the mechanism by which the latter occurs is more obscure. For practical purposes only rays below 3,000 A.U. may be considered abiotically active,³ and it has been shown that no rays below 3,000 A.U. reach the retina. However, it has been demonstrated by Duke-Elder⁴ that the abiotic effect in the retina can occur. It is probable that if this is caused by direct abiotic action the retina may be sensitized to rays longer than those to which it usually responds. Or it may be, as Birch-Hirschfeld⁵ suggests, that the changes are the result of an overstimulation of the physiologic mechanism of vision.

The literature concerning ultraviolet irradiation of the eyes is not extensive. Lear⁶ reported three cases of ophthalmia due to exposure to ultraviolet rays. He found a definite latent period (within 24 hours) between the time of exposure and the onset of the symptoms of pain and photophobia. The retina did not appear to be damaged in his cases.

Four cases of central retinitis from looking at a solar eclipse were reported by Makarov.⁷ He found that the scotomas appeared within 15 minutes, whereas the latent period in electric ophthalmia was much longer. In a detailed review of the literature, and a study of 11 cases caused by the solar eclipse in 1912, Klang⁸ found that in half of the cases there were central or paracentral scotomas, with denser central portions. He found that the ophthalmoscopic findings were not proportional to the visual disturbances, there being cases with scotomas but no fundus changes, and vice versa.

Epeleers⁹ made an exhaustive study of 13 cases of eclipse blindness during the summer of 1912. In 6 of these he found a ring scotoma, and in 11 there was a slight enlargement of the blind spot.

Four patients under observation by Carmazza¹⁰ showed, following observation of a solar eclipse, dark red maculas with radial gray striations, round white spots, and grayish surrounding retina. In three of the four cases all symptoms disappeared in a short time.

Ultraviolet irradiations of the eyes of rats by Reichling¹¹ produced severe reactions in the structures of the eye anterior to the retina but no mention is made of retinal changes.

Similar irradiation of rabbits' and guinea pigs' eyes by Rohrschneider¹² produced only corneal and lens changes.

It is probable, because of the relatively short exposure, that in the two cases reported in this paper temporary func-

tional changes in the retina or visual pathways resulting in contraction of the visual fields and temporary amblyopia were the result of the thermal action of the carbon-arc light. That this type of ultraviolet lamp may be sold over the counter without goggles or sufficient warning concerning the danger to vision is a condition which should be considered in the interest of the conservation of vision.

SUMMARY

1. Two brothers were exposed to an open carbon-arc lamp for three 15-minute periods within 48 hours. 2. Following

this, vision was reduced to the perception of hand movements and the visual fields to a temporal crescent in each eye. 3. There was gradual recovery in the course of 11 days, both of visual acuity and visual fields. 4. Consideration of effects of ultraviolet radiation make it probable that the contraction of the visual fields and temporary amblyopia in these patients were caused by the thermal effect of the carbon-arc lamp.

LESS EVIDENT CAUSES OF LOWERED ACUITY IN SENILITY*

INCLUDING A DISCUSSION OF A CASE OF ENDOTHELIAL DYSTROPHY AS THE CAUSE OF BULLOUS KERATITIS BY F. H. VERHOEFF, M.D., *Boston*

RALPH I. LLOYD, M.D.
Brooklyn, New York

Only those who have used the binocular corneal microscope of Csapsky, with its weak, diffuse illumination, can appreciate the genius of Gullstrand, who used the same binocular and by adding

It revealed details of corneal diseases that had previously escaped observation and diagnosis. Most of these triumphs concern younger persons, but the degenerative conditions of the postcorneal

Fig. 1 (Lloyd). Myopia of 6 diopters. Vision but little affected. Tension at times a few points above the high limit. The fibrin bits are numerous and, although they appear here as if limited to the central zone, are easily seen everywhere if the light is shifted.

the slit of light made the instrument next in importance to the ophthalmoscope.

* Read before the American Ophthalmological Society at Hot Springs, Virginia, June, 1943.

endothelium are peculiar to older patients. Pigmented dots in varying number may be seen upon the posterior corneal surface of many older patients by

Fig. 2 (Lloyd). Cornea farinata. Hyperthyroid, appearance sudden, moderate effect upon the vision. Lens changes followed in a few months.

retroillumination, but the eyes function well and the patient enjoys good vision. These deposits may increase in number or change in character, especially after cataract extraction, but even then cause no fears for the future of the eye. In some cases, with profuse discrete deposits, there is lowered acuity and occasionally slight rise of tension. After successful trephining, pigmented bits are deposited in large numbers on the posterior corneal and lenticular surfaces, with formation of synechiae and, although the distance vision may fall perceptibly, reading ability may be satisfactory. Forward movement of the lens and early cataractous changes are associated features, but the source of the deposits is

unexplained (figs. 1, 2, 3). A cloud of pigmented bits is an unfavorable omen in cases of diabetes, hyperthyroidism, or presenility.¹ An advanced state of this form of postcorneal pathology is the cornea guttata which Vogt asserts is the early stage of Fuchs's dystrophy.² This slitlamp picture is very clear, showing droplets and pigmented bits on the posterior surface and an increase in the number of Henle's warts.^{3, 4} There seems to be an endothelial degeneration which allows the aqueous to seep into the deeper layers of the cornea with subsequent trophic changes that feature Fuchs's dystrophy. The epithelium becomes edematous, sensation is lowered, and the cornea cannot withstand the ordinary ex-

posure of daily life. Minute pockets of fluid in the edematous epithelium tend to coalesce, forming blisters that become infected when the cover is lost, and the eye is ruined unless new tissue is formed be-

under the microscope and found the endothelial defects which permitted aqueous infiltration into the corneal stroma.

Dr. Verhoeff has sent me the following description of an unpublished case of

Fig. 3 (Lloyd). Slitlamp view of cornea guttata in a woman aged 74 years. Moderate reduction of vision, eyes uncomfortable.

neath the epithelium.^{5, 6, 7, 8} Protective devices may prevent ulceration and secondary infection, but, in any event, vision is very poor. In the early stage these patients may say vision is poor upon awakening but improves after being up and about. This improvement is due, apparently, to massage of the edematous epithelium by the upper lid. As is well known, each of these cases is one of potential glaucoma. Vogt studied such eyes

epithelial dystrophy in which he examined the eye microscopically 17 years ago: "The patient, then aged 75 years, was brought to me in 1926 by a young colleague. The left eye showed a typical picture of Fuchs's epithelial dystrophy. Its vision was markedly impaired, and there were mild symptoms of irritation. The other eye was slightly, if at all, affected. The irritation increased, and, finally, about six months later, became

so severe that my colleague removed the left eye and sent it to me for microscopic examination.

"A median vertical section of the cornea showed these changes: From the

and, where covered with 'endothelium,' was sharply defined. Near the center of the cornea, for a stretch of 3 mm., the 'endothelium' was entirely absent, and here the surface of the new layer of

Fig. 4 (Verhoeff). Section of cornea. Case of epithelial dystrophy. Upper periphery of cornea, showing small warts on Descemet's membrane and small defects in the abnormal endothelium. Elsewhere the changes were different and much more marked.

periphery above, for a distance of 0.75 mm. Descemet's membrane was slightly thickened and showed many warts, most of them small. Beneath it the 'endothelium' was greatly altered, and in minute areas, absent (fig. 4). Elsewhere there were no warts. At the periphery below, the 'endothelium' was completely absent for a distance of 0.75 mm. Behind most of the cornea, an additional layer of Descemet's membrane had been formed, about one half the thickness of the old. This was composed of an almost transparent substance that stained feebly

Descemet's membrane was fuzzy. Elsewhere the new membrane was largely covered with 'endothelium' which, however, was abnormal in that the nuclei were scanty, thin, and elongated. Probably the 'endothelium' had previously been lost here, and then poorly re-formed.

"On the anterior surface of the cornea, the epithelium was intact but, just below the center, was characteristically thickened as in bullous keratitis, and separated from Bowman's membrane in the form of a large flat bleb. Here, immediately beneath Bowman's membrane, were two

nodules, produced by proliferation of the corneal corpuscles. Each was about 0.25 mm. in diameter, and 0.12 mm. in thickness. In this region, in the middle layers of the stroma, there were a few fairly large blood vessels. From the corneal limbus below, fine vessels had extended for a distance of 0.75 mm. between the epithelium and Bowman's membrane—the merest trace of beginning pannus degenerativus.

"The eye showed no evidences of glaucoma—there were no peripheral anterior synechiae, nor was there the slightest cupping of the optic disc. The retinal ganglion cells were intact. The choroid showed very slight sclerosis of its vessels, and insignificant infiltration with lymphocytes. Otherwise the eye was normal except for common senile changes; notably, hyaline degeneration of the ciliary processes, and marked proliferation and degeneration of the pigment epithelium behind the macula.

"From these findings, I attributed the epithelial dystrophy to the changes in and loss of the corneal 'endothelium.' The 'endothelial' changes seemed to me analogous to senile changes of the pigment epithelium. First there had occurred senile hyperplasia of the 'endothelium,' producing in places a new layer on Descemet's membrane, and then degeneration with final denudation. No doubt, even before the denudation occurred, the altered 'endothelium' permitted the aqueous to permeate the cornea and affect the epithelium.* Finally the process led to bullous keratitis with secondary vascularization of the cornea. This case proves that formation of warts is not essential to the process—the hyperplasia of the endothelium may produce, not warts, but

duplication of Descemet's membrane. In this connection it is to be noted that just as colloid excrescences of the pigment epithelium may occur in young adults, so may cornea guttata. Whether the latter always ultimately produces epithelial dystrophy, I do not know, but certainly many years may elapse before it does so. Of course, the epithelial dystrophy is produced neither by warts nor by duplication of Descemet's membrane, but by the associated alteration of the 'endothelium,' and by this alteration only when it has become severe. No doubt, no two cases would be exactly alike in respect to the endothelial changes. The important fact is that epithelial dystrophy is produced by a degenerative change in the endothelium. Usually, this can be regarded as atrophic, even when the eye is not otherwise senile, but probably in some cases it is secondary to other changes in the eye. Any type of cataract operation injures the endothelium, more or less. In some cases, for unknown reasons, the injury is never fully repaired and epithelial dystrophy results. In some cases, the epithelial dystrophy is probably due to persisting contact of the vitreous and cornea. The reason why 'endothelium' is inclosed in quotation marks is because it is not really endothelium but 'mesenchymal epithelium.'"

Only the early stages of Fuchs's dystrophy are likely to escape notice. The first objective signs are anesthesia of the cornea with edema of the surface epithelium. Which comes first is a question, but the patient's attention is attracted by fading vision. There are no early characteristic symptoms of this syndrome but it is rarely seen in satisfactorily functioning eyes. The stubborn and troublesome group of symptoms usually diagnosed chronic catarrhal conjunctivitis, requires careful study to avoid missing early

* D. G. Cogan (Arch. of Ophth., 1941, p. 941) has satisfactorily explained how, under such conditions, vesicles and bullae are formed.

Fuchs's dystrophy (cornea guttata) and keratitis sicca (keratitis filamentosa). Treatment is fruitless and vision is lost as new tissue forms a protecting barrier beneath the epithelium (fig. 5). Fuchs has

tension and careful observation afterward. If there is the slightest evidence of elevation of tension, a trephining should be done with complete iridectomy. If the eye reacts well, the extraction

Fig. 5 (Lloyd). Slitlamp view of Fuchs's dystrophy in the early stage of epithelial edema.

reproduced this condition in animals by irrigating the anterior chamber, but that cannot explain the occurrence after cataract operation, when no irrigating has been done, irrespective of the type of operation.

Slitlamp study is a part of the routine before cataract surgery, and if cornea guttata is found, the operation should be performed with preliminary taking of the

should follow. If, later, this eye develops the characteristic changes of dystrophy with elevation of tension, the second eye should be operated on, despite the gloomy outlook, unless the changes in the corneal surface have already appeared. Measures to overcome rise of tension should be undertaken on the slightest provocation. Fortunately, many of the patients who have bedewing of the posterior corneal

surface, escape further trouble. In some, the changes are unilateral, at least for some years. It may seem that too much stress is placed upon the tension element, but the onset is so gradual that it may be overlooked at the time when treatment can give results.

A very similar corneal dystrophy occurs after cataract surgery (fig. 6). Whether this is latent Fuchs's dystrophy stirred

of fundus lesions escape the hand-scope now in common use. Red-free light and binocular ophthalmoscopy supply useful details in certain cases, but it would seem as if the limit of efficiency had been attained in this particular direction.

Until direct examination was made the easier of the two methods, there was room for difference of opinion as to many fundus cases. The better instru-

Fig. 6 (Lloyd). Epithelial dystrophy after operation for cataract. Advanced stage. Patches of edema with large irregular bleb.

into activity, or whether it arises *de novo* after operation, is not yet clear. Dr. Verhoeff's comment on this question is most illuminating and practical.

The ophthalmoscope came into use in 1851. It made ophthalmology a specialty and became at once the most important of our diagnostic instruments. About 25 years ago, the electric lamp was arranged for its illuminating system, making such an effective instrument that only details

ment and the pathologist have cleared up many hindrances to correct diagnosis, but many eyes with unusual lesions do not come to the laboratory, so our knowledge is not so positive as we would like. It behooves us to collect and compare our case reports, in order to create a reliable and informing literature.

An unobtrusive fundus picture seen among our older patrons is ushered in by high reflexes in the macular area (fig. 7).

The choroid looks "meaty" and the retinal capillaries are tortuous. The vision may be almost normal, although to the examiner's eye the retinal surface throws a sheen like watered silk. The binocular ophthalmoscope will show the uneven surface of the retina as the finer vessels cross the affected area. When the sheen is very strong, the vision falls and red-free light shows this flare to be a lacy film in the retina. A few of these eyes under observation have developed a hole in the macula after slight accidents or spontaneously.

This condition has been seen in diabetes, and vitamins A and B seem to be of definite value. They were prescribed to supply the deficit occasioned by elimination of starch and sugar from the diet and the diabetic's inability to use fats. Other patients get along as well with or without vitamins. I do not know of any eyes of this type examined by the ophthalmoscope and later by the pathologist. Judging from Kuhnt's description⁹ and the later appearance of the hole in the macula in these cases, this is probably the rarefying atrophy of the retina he described. While this change is going on, it is not unusual to see a thinning of the tapetum in the nasal fundus, exposing the deeper choroidal vessels with early sclerotic changes here and there.

Another senile change in and about the macula is the appearance of small pigmented spots in the macula some time after the patient has complained of a feather or a "bug" near the fixating point. At first, the annoyance occasioned is out of proportion to the effect upon the patient's ability to read test type, but later a definite scotoma appears with corresponding loss of vision. It is doubtful if the pigment spots which eventually may be very clearly seen in the macula are causing the loss of vision; they may rather be an indication of disease in the

pigment layer and in the rods and cones, of which process the pigment is a by-product. Both eyes are usually affected but the disease may appear in one eye first or make more rapid progress there. This condition has occurred in patients with failing memory, mental and physical

Fig. 7 (Lloyd). Fundus of an elderly person with retinal reflexes, tortuous finer vessels in macular area and "meaty" choroid. After a slight head bump, the hole in the macula appeared.

deterioration usually called "softening of the brain." Similar macular defects occur in cases of cataract. If the lesions develop after the operation, the loss of central vision may precede the objective signs. If the defects are found after a successful cataract operation, the question may arise whether they are also present in the eye that has not been operated upon. The light-projection test will not decide this, but the patient must always be given the benefit of the doubt.

The original technique of perimetry was so tedious and the value of colored test objects so questionable that the natural preference for objective evidence led to relegation of the procedure.

Bjerrum introduced his system of quantitative perimetry and campimetry

Fig. 8 (Lloyd). Patch of degeneration in optic nerve of an aged person (Fuchs. Arch. f. Ophth., 1920, v. 103. Ueber senile Veränderungen des Sehnervens).

placed glaucoma diagnosis upon a scientific basis and provided a practical technique for general use.

Perimetry is of greatest value in demonstrating and localizing lesions behind the globe. Lesions anterior to the optic thalamus have an effect upon the optic disc, but the farther back the lesion, the later does the atrophy appear. There are diseases along the optic pathways behind the globe which have no effect upon the disc but few of these belong to the group we are discussing.

Although the effects of entanglement of the chiasm under tension in the circle of Willis have been well studied in pituitary disease, this peculiar complication was more recently recognized in tumors of the brain with distention of the third ventricle pressing upon the chiasm from above.¹⁰ Demonstration of local pathology in the optic nerves of older patients and the pernicious effects of pressure by sclerosed members of the circle of Willis was the work of Fuchs and Liebrecht.^{11, 12} Fuchs examined the optic nerves and chiasms of a group of old persons and found amyloid deposits among the nerve bundles, patches of fibrosis in the nerves, and pressure damage at the inner margin

with serial white test objects in 1889, but some years passed before the idea reached us. The first Bjerrum scotoma reported in our ophthalmologic literature is the work of Dr. Harry Friedenwald in 1902. Dr. Luther Peter's campimeter imposed a practical demonstration that the field defects of glaucoma had been missed entirely because the profession insisted upon using the perimeter for purposes it could never satisfy. The Bjerrum method

of the optic foramen where the nerve was pressed against the fibrous margin of the canal entrance by the sclerosed ophthalmic artery. Liebrecht made extensive studies along the same lines and found the patchy degeneration in the nerves between the chiasm and the globe (figs. 9, 10). He also found the damage described by Fuchs at the entrance of the optic nerve into the optic canal, and advanced changes where the anterior cerebral artery and the ophthalmic artery, branching from the carotid, had indented the nerve near the chiasm. The one thing we lack is a systematic examination of such eyes in life as well as the pathologist's report. There are none of these available, so far as I know, and we are not in a position to say that a certain visual-field defect in an older person is caused by a certain patch of sclerosis in the macular bundle of an optic nerve or pressure of a sclerosed artery at a certain place in the

Fig. 11 (Lloyd). Vision with correction 15/30 and 15/20 despite very contracted fields. Fundus negative except the ordinary changes of vascular sclerosis in moderate degree.

cranium near the chiasm. Comparison of field defects in pituitary disease, chiasmal arachnoiditis, and brain tumors with those found in old people explain many cases formerly quite blank. Older people often complain of difficult vision but may read Snellen and Jaeger test type very satisfactorily. The fundus gives no clue

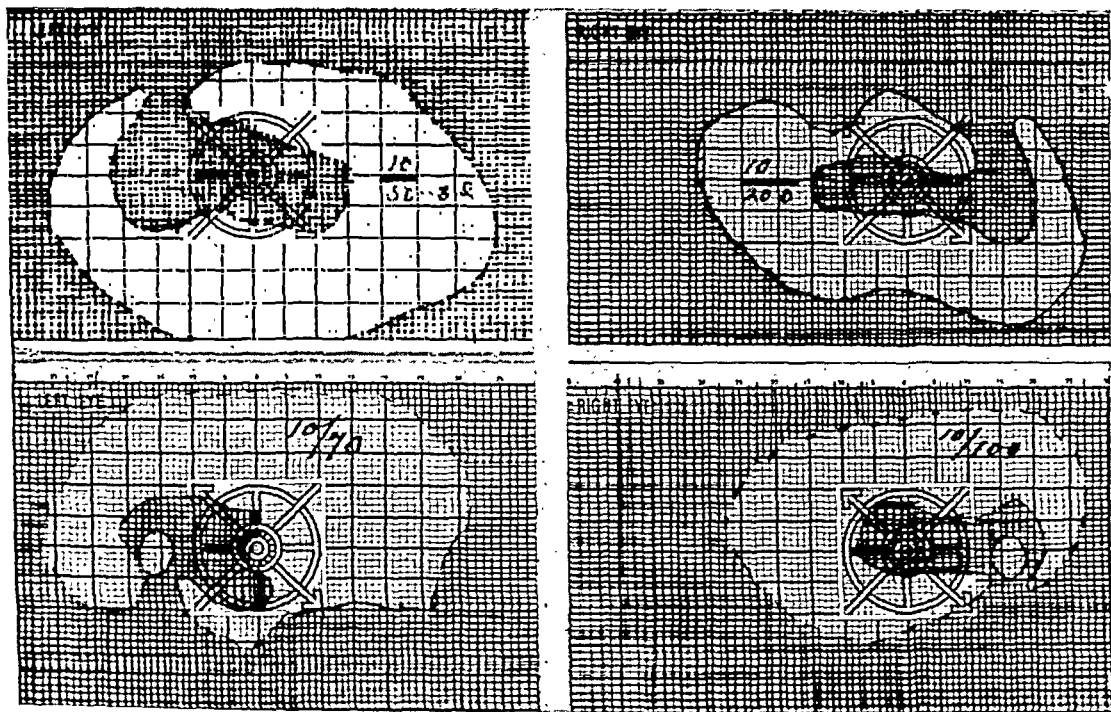

Fig. 12 (Lloyd). Contracted fields with central scotomas in older persons. Vision 10/50 and 10/200; 10/70 and 10/100.

whatever but the visual fields are very much contracted and the blind spots enlarged (figs. 11, 12). These patients are usually angiosclerotics and not infrequently are victims of vascular accidents

Fig. 13 (Lloyd). Left homonymous hemianopia came on during sleep without other complaints than difficult vision. O.U. 20/20 less a few letters with correction. One degree white test object.

later. Central vision may fail later and then, in addition to the contracted fields, there is a central scotoma extending from the blind spot to and including the fixating area, later to break through to the periphery, above or below the blind spot. The sclerosed ophthalmic artery pressing against the optic nerve may explain the constriction of the field, but the most reasonable explanation of the bilateral central scotoma is a patch of sclerosis in the center of each papillo-macular bundle. The cases with progressive atrophy of the nerve of one or both eyes would fall into the group of lesions caused by pressure of the carotid artery and its branches or to extensive degenerations extending up or down in both optic nerves.

Knapp¹³ has discussed another phase of this condition with atrophy of the optic nerve, bizarre field defects, and cupping of the discs but without elevation of tension. This problem vexed von Graefe and Donders, who did not have reliable tonometers nor local anesthetics. When tension was evident to the fingers, it was called glaucoma simplex, but otherwise

it became cupping of the disc with amblyopia. Bjerrum demonstrated that careful field taking in many of these cases revealed the typical defects of glaucoma despite the low tension. Effort has been made to show sclerosis of the circle of Willis by the X ray, but the results are not satisfactory as yet.

Hemianopias caused by vascular accidents behind the thalamus have been studied in life and also in the laboratory. They have been consistently overlooked in practice since the practical Bjerrum technique came into use, because of the fixed idea that these defects are rare and cannot exist unless the patient has been seriously ill, or has lost much of his vision. Hemianopias due to lesions in the right optic radiation behind the thalamus can occur without loss of central vision, without illness, and with little inconvenience to the patient except that he cannot see well but does not know why. Any patient who has been in coma from whatever cause (uremia, apoplexia, sleeping sickness, difficult nitrous oxide anesthesia, or carbon-monoxide poisoning), especially an older person, may upon awakening complain vaguely of his vision, which should occasion a field study. The most common apoplexies concern the arteries of the internal and external capsule, but hemianopia is not a symptom of this anterior lesion. The most common hemianopias are due to lesions of the branches of the posterior cerebral artery. Lesions of the Sylvian artery may produce aphasia and disturbances of memory, but there will not be hemianopia unless the deep terminal branches are also involved. It is most desirable that we add to our clinical knowledge of lesions involving the optic radiation and its cortex; the greatest need, however, is to make our literature truly scientific by thorough study of the fields and vision of older patients in institutions where

autopsies are permitted and where there is an adequate staff of special examiners. At this time, all of our institutions lack sufficient help, but the return of peace may permit resumption of the many avocational activities of our medical men, of which the public knows nothing.

I would like to emphasize the statement that hemianopias are not uncommon,

that they occur without serious illness, and that the patient's complaints may be vague and seemingly unimportant. The vision may be 20/20, or nearly so, and any vascular incident, however insignificant, should suggest study of the visual fields.

CANCER OF THE EYELID*

LESTER HOLLANDER, M.D.
Pittsburgh, Pennsylvania

AND

FRANCIS J. KRUGH, MAJOR (MC), A.U.S.
East Point, Georgia

GENERAL CONSIDERATIONS

Cancer of the eyelid is a frequent disease. In a group of 2,601 patients suffering from cancer of the skin in one form or another and treated at the Pittsburgh Skin and Cancer Foundation, 239 had cancer of the eyelid. Thus, in an unselected group of patients suffering from skin cancer, cancer of the eyelid occurred in 9+ percent of instances.

Like tumefactions in any other location, cancer of the eyelid presents its own particular problems. These include that of diagnosis, of prognosis, and of therapeutic approach. It is the last-mentioned consideration, however, which most interests both patient and physician and affects the problems of diagnosis and prognostication.

The goal of treatment is the complete eradication of the new growth. This is to be accomplished in the shortest possible time, with the least amount of inconvenience to the patient, and with as little damage as possible to the eyeball, the tear ducts, and to the lids themselves, so as not to interfere with the ease, comfort, and function of all these structures. To take care of all of these contingencies it is of inestimable value that a variety of procedures is available for the purpose of complete destruction of a new growth.

These procedures include both surgical and nonsurgical methods. Surgical procedures consist of: 1. Ordinary excision.

2. Removal with the so-called radio-knife.
3. Destruction of the tumor by electro-desiccation or electrocoagulation.

The nonsurgical field offers: 1. A variety of modalities of X ray: a. Superficial. b. Contact. 2. Radium: a. Topical application. b. Insertion of emanation or radium needles.

PURPOSE OF COMMUNICATION

The purpose of this communication is to discuss the methods of treatment and to endeavor to show both by illustration and statistical evaluation the irrefutable fact that it is not a particular method of treatment which determines the ultimate result, but that, in the final analysis, it is the adaptation of a procedure to the patient rather than the opposite which must be foremost in the mind of the physician.

In the accumulation of the material for this report only 125 of the 239 cases were finally chosen, chiefly because of incomplete histories and the absence of follow-up. Although this number is small, it serves to emphasize the previously stated therapeutic axiom.

ANATOMIC CONSIDERATIONS

Delineation of the scope of the location of eyelid cancer was accomplished by the utilization of the fact that adipose tissue is not found ordinarily in eyelid structure.

Eyelids comprise the two thin movable folds of skin and mucous membrane in front of the eyeball and are placed there for such protection as they may offer

* From the Pittsburgh Skin and Cancer Foundation.

against injury, foreign bodies, light, and the like, this protection being accomplished by their closure. Eyelids are composed of the following structures: The skin, areolar tissue, fibers of the orbicularis oculi muscle, tarsus, tarsal glands, and the mucous membrane, the conjunctiva itself. The upper eyelids contain, in addition, the aponeurosis of the levator palpebrae superioris muscle. The skin covering the eyelids is very thin and extremely flexible. The junction with the mucous-membrane layer of the palpebral conjunctiva is more acute than are similar junctures at the vermilion border of the lips and about the mucocutaneous junction of the external genitalia and the anal orifice. However, this mucocutaneous "seam" of the eyelid does not seem to be as frequently the site of malignant cellular changes as are those in the other locations. Within the skin itself we find the usual appendages, sweat and sebaceous glands, hair follicles from which grow lanugo hairs, and also the short, thick outward-curving cilia. The subcutaneous tissue is referred to as being areolar. It is loosely and delicately constructed and, as previously stated, it does not ordinarily contain fat, and is thus used as definitive in determining the extent of the eyelids themselves.

Likewise the palpebral commissures, both inner and outer canthi, are important delineating landmarks. Tumors located at the inner canthus, one of the most common sites of eyelid cancer, were found to extend over the side of the bridge of the nose rather than to extend toward the tarsal plate of the eyelid. Here again it was noted that the thin loose areolar skin without fat marked the scope of the rigid portion of the eyelid as it extended over the bridge of the nose. Thus, to recapitulate, cancer of the eyelid was considered as such when it was apparent that it arose from that portion

of the skin and mucous-membrane fold which contained no fat in the subcutaneous structures.

Cancer may occur at any portion of the eyelids, upper or lower, or at the inner or outer canthi. The distribution of cancers in the 125 patients under consideration was as follows: 17 on the upper eyelid, 47 on the lower eyelid, 52 at the inner canthus, and 9 at the outer canthus.

MORPHOLOGIC CONSIDERATIONS

The tumors varied considerably in their appearance. Some were but small nodules which protruded from an unaltered skin surface, enlarged very slowly, and could be recognized as cancers only by the fact that they were extremely hard. Some of the tumors were similar to those just described and varied only because of the atrophy of their covering epidermis. In some instances the normal skin tone was replaced by a waxy sheen which was soon recognized as being as pathognomonic as the stony hardness of carcinoma. In a number of instances the surface of the tumor was traversed by newly formed telangiectasia. Another type of tumor surface appeared studded by warty excrescences. In this type, usually because of the difficulty of removing the accumulated soiled epidermal debris, the lesion was discolored, grayish black, or it assumed a completely darkened appearance. In some of the tumors localized necrotic areas were predominant features. One or more small or large, deep or shallow, and usually uneven ulcerations were present, covered by a loosely glued various-colored encrustation. In the larger tumors, where localized cellular death had assumed larger proportions, the entire tumor area was at times destroyed, and the encrustation hid from view the base of the entire ulcer. Dependent on the amount of bleeding

that occurred through erosion of the superficial vessels, the color of the crust would vary. This encrustation, when it became heavy, would exfoliate of its own accord, expose the underlying ulcer bed, and then re-form as the drying effect of the atmosphere would concentrate suppurative, hemorrhagic, and necrotic material into a semisolid, loosely adhering but pliable surface cover. These processes of crust formation, exfoliation, and re-formation would follow each other at irregularly spaced intervals. Sometimes,

due to injury of some type or other or just because of the spreading necrotic process, minor hemorrhages would occur, and as they lasted shorter or longer periods the tinctorial effect on the overlying crusted structures would manifest itself in various degrees. Some of the tumors had a fleshy appearance, the surface being irregular because of retractions occurring at unexpected locations. In one instance a black-pigmented, shiny, flat nodule occurred about the center of the lower eyelid. The ominous black fore-

told the seriousness of the condition, for it proved to be an example of melanocarcinoma, the most dangerous and almost always fatal type of new growth.

DIFFERENTIAL DIAGNOSIS

It is apparent from the perusal of the foregoing description that eyelid cancer has a multiform appearance, and clinical differentiation from tumefactions other than cancer is essential.

Pigmented hairy moles offer difficulty only from the standpoint of differentiating them from melanocarcinomas. One can depend on the admixture of brownish color and presence of the hair-bearing areas as points against malignant melanotic tumors. Especially the latter point, the presence of hairs over the surface of the tumor, is of inestimable value in this differential diagnosis. Melanocarcinomas, as a general rule, do not present such hair-bearing areas.

Vascular tumors, such as the ordinary variety of hemangiomas, may confuse the issue only until their composition of vascular structure is ascertained.

Small warty excrescences, the so-called filiform warts, occur with great frequency in older individuals. These little tumors are usually multiple and appear as pouchlike prolongations of various size. The important physical sign is the absence of hardness. It is supposed that they result from the loss of elasticity of the skin of the eyelids.

Yellowish and brownish flat multiple tumors are found in older individuals, whose forehead and face, as a general rule, are covered by these small tumefactions. These are examples of so-called seborrheic wart. Darker and somewhat harder nodules, the so-called senile keratoses, occur also and may be precursors of cancer of the eyelid.

Soft, yellow, oval, single or multiple tumefactions, the result of fat-cell deposits, are called xanthoma palpebrarum and are easily differentiated from cancer of the eyelid by the distinctive yellow color and the absence of the pathognomonic hardness of cancer.

Umbilicated, multiple, smaller or larger tumefactions of molluscum contagiosum may at times cause confusion. The rapidity of the growth and the spread, the presence of inflammation about the older lesions, the otherwise unaltered character of the adjoining skin surface, the absence of hardness, and the presence of itching will serve as differentiations.

Such tumefactions as that produced by chalazion or other chronic nodular localized inflammatory conditions will need thoughtful consideration from the standpoint of differential diagnosis. The most important one of these occurs as a small nodule at the margin of the eyelid and persists for a long period, remaining unaltered in size and unassociated with pain or tenderness. The firmness of the surrounding connective-tissue bands within which it is located endows the lesion with that nonelastic hardness which resembles the stony hardness of eyelid cancer. The microscopic picture presented by this type of tumefaction has been interpreted as a form of tuberculous reaction. We have encountered this lesion a good many times. Repeated guinea-pig inoculations, however, failed to prove it as caused by the tubercle bacillus. Thus, as the result of this negative bacteriologic finding, we have come to consider this eyelid tumefaction as an example of a foreign-body reaction, perhaps due to the inclusion of a broken hair shaft or some such substance within this area. We have no proof of this contention, but no other explanation seems as rational. We have found that this particular type of nodule can be

differentiated only by microscopic investigation.

MICROSCOPIC CLASSIFICATION

Whenever and wherever it is possible all of the tumefactions about eyelids should be studied with the microscope.

Classification of eyelid cancer according to microscopic appearance falls into four groups: (1) the basal-cell or hair-matrix type, (2) the squamous-cell or epidermoid type, (3) the mixed-cell type, and (4) the melanoma group. The importance of knowing the type of eyelid cancer under consideration is not only of academic value but has important connotations from the standpoint of prognosis. Parenthetically speaking, a completely removed basal or hair-matrix type of cancer should result in no further annoyance to the patient. Chances of recurrence should be practically nil. On the other hand, one may not be nearly so optimistic when one of the other three types of eyelid cancer has been discovered, for in spite of the greatest care and most meticulous elimination of these new growths, recurrences are not only possible but, in instances, even likely. This, of course, is especially true of the last group mentioned, the so-called malignant melanotic tumors.

Of the 125 eyelid cancers, 60 were classified according to their microscopic appearance. Of these, on the upper eyelid, 2 were basal celled and 4 were of the epidermoid-cell variety. On the lower eyelid, 16 were basal celled, 7 were epidermoid celled, 1 was mixed celled, and 1 was a melanoma. At the inner canthus 24 were basal celled and 2 were of the epidermoid-cell variety. At the outer canthus 3 were of the basal-cell type of carcinoma. Thus, of the 60 so analyzed, 45 were found to be of the basal-cell type, 13 were of the epidermoid-cell type, 1 was

of a mixed-cell type of carcinoma, and 1 was a melanoma.

It is indeed fortunate that the preponderance of eyelid cancers proved to be of the basal-cell or hair-matrix-cell variety. The proportion was 3 to 1. It is fortunate because this type of carcinoma is usually but locally malignant and lends itself readily to complete removal. This is especially true if it is treated early. Recurrences are due either to faulty removal or to the fact that the tumors have so invaded the surrounding structures that no therapy can accomplish the desired effect.

STATISTICAL CONSIDERATION

Of the 125 patients under consideration, 79 were men and 46 were women. Their ages ranged from 25 to 80 years. The seventh decade of life furnished 47 of the 125 patients, while 82 were found to be in the age group from 55 to 74, showing that the preponderance of the cases occurred in the aged patients.

The duration of these tumors was difficult to ascertain for several reasons: (1) Because patients, as a general rule, are forgetful, (2) because they are unobserving, (3) because these tumors were so inconsequential at times that they did not merit the fixation of the time of their first observation, and (4) because of the so frequently inherent optimism of patients, which tends to permit anatomic abnormalities to go unnoticed. However, we did find that 41 patients reported the duration of the lesion to be from one to two years, thus placing one third of these tumors in that particular duration bracket, which seems reasonable and worthy of acceptance.

One other observation is of importance. This concerns itself with multiplicity of lesions. While numerous cancers of the skin of the same individual

are not an infrequent finding, cancer affecting the eyelid was a single entity in all instances. We attach a good deal of importance to this fact.

TREATMENT

The object of treatment, of course, is the complete eradication of the cancer present. This is to be accomplished with as little interference with function and with as little damage to the surrounding structures as possible.

SURGICAL TREATMENT. Whenever and wherever it is possible, cancer of the eyelids should be excised. This permits thorough microscopic examination, and invaluable information is gained as to the type of tumor and completeness of removal, both of which have, of course, a most important bearing on prognosis.

Excision is not possible if the tumor has invaded the surrounding structures to such an extent that the tumor cannot be freed and resected. Further difficulty with excision arises in the repair of the damage caused. Repair must be of such nature that the eyeball is not exposed unduly and that the eyelids are so reconstructed that their function is effectively maintained. When the entire thickness of the eyelid is involved in the neoplastic process, repair becomes difficult, but when the cancer is more superficial and freely movable, little difficulty is experienced because the loose and somewhat lax skin covering of the eyelids is easily shifted to cover the skin defects.

In carrying out surgical repair one must bear in mind at all times the following considerations: (1) that careful repair of the palpebral conjunctiva when it has been damaged is imperative; (2) that the proper support of the eyelids depends on properly reconstructed tarsal plates; (3) that eyelid-margin distortions

which could cause the inversion of the cilia are to be carefully avoided; and (4) that undue scarring is followed by retractions and the formation of an ectropion, and that this is also to be carefully avoided.

Repair of lesions excised from the region of the inner and the outer canthus offers fewer difficulties. This is due to the fact that although direct closures in many instances cannot be resorted to, pedicle grafts cut from adjoining skin surfaces are easily accomplished. These grafts can be obtained from the region of the glabella or the temporal area, depending on whether the damage is being repaired at the inner or the outer canthus, respectively. Our procedure in carrying this out is as follows:

An appropriately sized portion of skin is cut out, leaving a reasonably sized pedicle attaching it to the adjoining skin. The graft is transferred to the site of the excised area by a half twist of the pedicle. It is sutured into position by fine twisted silk and interrupted sutures and then bandaged in such a manner that pressure over the graft is maintained by means of a roller bandage of proper size. A wide elastic bandage is then wrapped about the head to insure the relative immobility of the dressing. One must be careful not to permit direct pressure to be applied to the eyeball; nor should the cilia be inverted during this procedure. A dressing of this type is kept in position for a period of five or six days, thus giving the graft an opportunity to adhere to the surfaces which have been uncovered by the operation.

Failures of takes from such pedicle grafts occur rarely, but when they do a variety of causes may be operative: These are as follows: (1) The pedicle is too narrow; (2) bleeding areas are not properly controlled, thus permitting an ac-

cumulation of hemorrhage under the graft which interferes with its adhesion; (3) the pressure applied is inadequate; (4) the dressing is removed before the fifth or sixth day. This last is exceedingly important. Sutures may be removed at the time of the first dressing, but the pedicle is permitted to remain for a period of at least three weeks. It is then easily removed and the final minor repair of the attachment is carried out.

Thirty-five of the 125 tumors were treated in this manner. Of these, 4 were of the upper eyelid, with 3 good results and 1 bad result; 16 were of the lower eyelid, with 13 good results and 3 bad results; 13 were of the inner canthus, with 12 good results and 1 bad result; 2 were of the outer canthus, both with good results. Thus, of the 35 surgical-scalpel excisions, 30 yielded good results and 5 bad results. Of the 5 bad results, 1, of the lower eyelid, was incompletely resected; 1, of the lower eyelid, yielded a malignant melanoma which terminated fatally; in 1, of the lower eyelid, the result could not be ascertained, for the patient failed to return; and 2, 1 of the upper eyelid and 1 of the lower eyelid, did not permit evaluation on account of the lack of sufficient time since operation.

Radio-knife excision followed by repair with pedicle grafting was carried out in 12 instances. It was a valuable method because it caused less hemorrhage and less shock and because it could be done quickly. Of the 12 patients thus treated, 2 had cancer of the upper eyelid, and both obtained good results. Six had cancer of the lower eyelids; we obtained good results in 4 and bad results in 2. Four patients had cancer of the inner canthus, in 3 of whom we obtained good results and in 1 a bad result. Thus, of these 12 patients, in 9 instances the results were good while in 3 instances they

were unsatisfactory. As the cancers treated by this method were extensive in size and considered not suitable for excision with scalpel, the high percentage of bad results is at least partially explained.

In another group of cases, in which the growth occurred at the inner canthus, excision with either scalpel or radio-knife surgery was not possible. In this group we found the cancer of the canthus to be of infiltrative character, and the tumors were firmly fixed to the fibrous structures of the surrounding area. The lesions themselves were immovable and firm. These patients were treated with *electrodesiccation*, unipolar diathermy being used for this purpose. After the tissues were thoroughly charred they were removed with a curette and the desiccated area painted with mercurochrome or, more recently, powdered with sulfathiazole and permitted to heal by granulation. Even after extensive electrodesiccation the scars obtained were highly satisfactory.

Such electrodesiccation was carried out in 13 cases. In the 1 instance of the upper eyelid a satisfactory result was obtained; of the 3 instances of the lower eyelid, only 2 satisfactory results were obtained; while of 8 instances at the inner canthus 4 satisfactory results were obtained; and in 1 instance of the outer canthus the result was unsatisfactory. Thus, of the 13 cases, 7 yielded good results while 6 yielded bad results. In the consideration of the high percentage of bad results, one must take into account the fact that only the inoperable type of cancer was subjected to this form of therapeutic approach.

In three instances the eyelid carcinoma was so extensive and so invasive that, in addition to electrocoagulation, enucleation of the eyeball was found imperative. One of these cancers occurred on the

lower eyelid, one at the inner canthus, and one at the outer canthus. None of these patients was helped by this treatment, and their disease resulted fatally.

NONSURGICAL TREATMENT. There were a number of reasons which prompted the use of methods other than surgical. These included the following: (1) The cancer was considered inoperable on account of its extension and size; (2) the patient was considered a poor operative risk; (3) the patient refused operation. In these instances X-ray irradiation was used in some form or other.

At first we used superficial unfiltered X ray, using lead foil as a shield both for the unaffected skin surfaces and over the eyeball itself. We experimented with a variety of doses from 350 r to 3,500 r in single or multiple treatments. After considerable trials we evolved a procedure which we use now and which we consider valuable. This procedure comprises the following steps:

An eye shield consisting of a soft lead-alloy material* is used for eyeball protection. It has an inner smooth concave surface to fit the contour of the eyeball and an outer convex surface to which a small projection is attached for the purpose of handling it. This eye shield is sterilized by allowing it to remain in 70-percent alcohol for 10 minutes and then placing it in sterile water for 5 minutes to remove all traces of alcohol. Sterilized mineral oil is then dropped upon the concave surface to act as a lubricant. The shield is held by the tiny grasping projection and is inserted between the eyelids: one edge is gently but firmly placed under the upper lid; then by pulling down on the skin of the lower lid, the other edge is permitted to slip under the lower lid. Various sizes of these shields

are required on account of the variability of palpebral apertures. Patients seem to tolerate this shield much better than they do the lead foil which we used before we became acquainted with this later type of protection. After the shield is placed in position the unaffected skin is covered with lead foil or leaded rubber and the treatment with the X ray is begun.

Recently we have utilized the so-called contact X ray instead of the ordinary superficial modality. We have obtained this energy from a Chaoul type of tube which has a focal roentgen-ray skin distance of 3 to 5 cm., depending on the length of the applicator used. The Chaoul tube is so constructed that the cathode is located at the tip of a cylindrical projection over which the applicators are placed. Between the target and the lesion there is a thin filter, consisting of 0.5 mm. of nickel window, which is needed to confine the water that circulates about the cathode as a cooling agent. A variety of applicators is available. This type of irradiation provides intensive local reactions, but the depth of the reaction is relatively short. It is this factor that makes it ideal for use in eyelid carcinoma. Because the skin and areolar structures of eyelids are thin, the opposition to the passage of superficial X rays of the ordinary variety is ineffective, and the deeper structures may be damaged unnecessarily.

Daily treatments of 500 r each were given. These treatments ran from 10 to 20 in number, depending on the severity of the reaction produced. Usually after the sixth treatment a softening of the tumor and a beginning inflammatory reaction were noted. Following this there was a gradual flattening of the lesion, and over the tumor site a superficial yellowish moist ulceration developed which was surrounded by a reddened and swollen sharply demarcated inflammatory zone. When this occurred, usually between the

* Supplied by V. Mueller & Co., Chicago, Illinois.

tenth and twentieth exposure, treatment was stopped. The reaction lasted from four to six weeks, then it subsided. Occasionally a course of treatments had to be repeated.

If the contact Chaoul tube for irradiation is not available, superficial X ray may be used. We have given 350 r with superficial X ray to carefully shielded areas in daily treatments until the development of a severe enough inflammation to conform somewhat to the type produced by the contact tube. Usually this requires about 10 consecutive daily treatments. As previously stated, both the depth and the width of the destructive reaction is greater with the ordinary superficial type of X-ray therapy.

Thirty-eight patients were treated with X ray. Of these, 17 were treated with the Chaoul contact modality. Of the 21 tumors treated with the ordinary superficial X ray, 6 were of the upper eyelid, 4 with good results and 2 with bad results; 6 were of the lower eyelid, 2 with good results and 4 with bad results; 7 were at the inner canthus, all with good results; 2 were at the outer canthus, 1 with good result and 1 with bad result. Thus, of the 21 patients so treated, in 14 instances good results and in 7 instances bad results were obtained.

Of the 17 tumors treated with the Chaoul contact type of X ray, 1 was of the upper eyelid, with a bad result; 5 were of the lower eyelid, all with good results; 8 were at the inner canthus, 6 with good results, 2 with bad results; 3 were at the outer canthus, 1 with good

results and 2 with bad results. Thus, of the 17 patients treated with the contact X ray, in 12 we obtained good results and in 5 bad results.

We treated but one patient with radium. His lesion was at the inner canthus. The result was unsatisfactory.

There were instances in which we had to use several methods of treatment—excision, electrodesiccation, roentgen ray, and radium. Various combinations of these procedures were used. In all, 23 tumors were so treated. Of these, 3 were of the upper eyelid, with 2 good results and 1 bad result; 10 were of the lower eyelid, with 7 good results and 3 bad results; 10 were at the inner canthus, 8 with good results and 2 with bad results. Thus, of the 23 patients treated with a combination method, we obtained good results in 17 and bad results in 6 cases.

Recapitulation shows that of the 125 patients, good results were obtained in 97 patients, unsatisfactory results in 28, for one reason or another. We further learned that no method yielded more satisfactory results than others and that the method of therapeutic approach depended on extent, operability, or the willingness of the patient to undergo certain procedures.

However, the general impression we gained was that the most satisfactory results were obtained from scalpel excisions or contact X ray, using the special shield which was described.

RECESSION OF THE INFERIOR-OBLIQUE MUSCLE FROM THE EXTERNAL-RECTUS APPROACH*

GEORGE P. GUIBOR, M.D.

Chicago

Overaction of the inferior-oblique muscle as a result of a paralysis of the homolateral superior-oblique muscle, or of the contralateral superior-rectus muscle, is not a common condition. Nevertheless, it may cause a hypertropia or ocular torticollis. When it causes these conditions and does not respond to treatment with prisms,¹ then surgical correction is necessary.[†]

This operation has been discussed by White,^{1, 2} who believes that it is indicated for the following purposes: 1. To correct a secondary deviation (of the inferior oblique) caused by a paresis of the superior rectus of the fellow eye. 2. To correct the secondary contraction due to paralysis of the superior-oblique muscle of the same eye.

At the suggestion of Dr. Frederick A. Davis of Madison, Wisconsin, that a procedure for a recession of the inferior-oblique muscle be studied and systematized, the author for the last five years has compared the results secured by myectomy and tenotomy with the results obtained by recession of the overacting inferior oblique. The results of this study will be presented in a later paper. The technique and procedure, however, of the recession of the inferior oblique will be presented here.

The procedure for the recession of the inferior-oblique muscle from the external-rectus approach after being worked

out on the cadaver was then performed successfully on patients. The result obtained was a satisfactory reduction of the overacting of this muscle followed by reduction of the hypertropia and in most instances by decrease of torticollis.

Recession of the inferior oblique can be performed under either local or general anesthesia.

PROCEDURE

Step 1, Incision. An 8-mm. vertical incision, 3 mm. from the external canthus, is made through the conjunctiva, but not through Tenon's capsule (drawing A). The longitudinal fibers of the external-rectus muscle can be seen through the vertically appearing tissue of Tenon's capsule over the muscle (drawing B).

Step 2. The incision is extended through the three layers of Tenon's capsule down to the external-rectus muscle. This muscle is dissected from the lateral bands of Tenon's capsule so that the strabismus hook can be inserted below it (drawing C).

Step 3. A suture is placed through its insertion as close to the sclera as is possible (drawing D).

Step 4. The external rectus is gently freed from the globe by nicking the central fibers of its insertion in the tissue between the sutures and the sclera, and by spreading the blades of the scissors. This method prevents cutting the sutures in the insertion and conserves the tissue. The external-rectus muscle when freed is gently pulled laterally and away from the globe (drawing E).

Step 5. While the bulb is rotated nasal-

* From the Department of Ophthalmology, Children's Memorial Hospital. Presented before the Indianapolis Academy of Eye, Ear, Nose, and Throat, April 22, 1943.

† The nonsurgical treatment of the less severe of these insufficiencies will be presented in a later paper.

ly by fixation forceps grasping the stump of the insertion of the external rectus, a squint hook with its rounded point downward is gently inserted below the globe until its curved edge touches the floor of the orbit. This tissue which becomes engaged upon the forceps contains the inferior-oblique muscle imbedded in the fibrous connections joining it with the external rectus (drawings F and G).

Step 6. The inferior-oblique muscle is now freed from the inferior-rectus muscle as the former is gently pulled upon to expose it to view. This procedure depresses the posterior pole of the globe and elevates the anterior pole if the globe is held in adduction by the surgeon (drawing H). The fibrous connections between the external-rectus muscle and the inferior-oblique muscle are definite, thick bands (drawing H), as are similar connections between the inferior-oblique muscle and the inferior-rectus muscle (drawing I). These bands between the three muscles must be dissected free if a recession of the inferior-oblique muscle is to be done. (They should not be freed if a myectomy or tenotomy alone is contemplated or else a complete lack of function will result.) Meanwhile, a test is made to separate the action of the inferior-oblique muscle from that of the inferior-rectus muscle, as follows:

The rounded edge of a second squint hook is placed in the lower conjunctival sac to push the globe down and in as the pull on the hook below the inferior oblique is decreased (drawing G). Gradually the pressure on the hook in the lower cul-de-sac is released as the pull on the hook below the inferior oblique is gently increased. If the inferior oblique is on the hook isolated from the inferior rectus, the anterior pole of the eye will travel upward (drawing H). As the hook in the cul-de-sac is removed completely the gen-

tle traction on the hook below the inferior oblique is increased, and the anterior pole will travel upward to a fixed position. This test for the presence of the inferior oblique when positive will tell the surgeon that the inferior-rectus muscle is not on the hook and therefore prevent the surgeon from cutting the inferior-rectus muscle, which could easily be done were both engaged upon the strabismus hook. When this test discloses that only the oblique muscle is on the hook and after this muscle is freed from the fibrous bands seen in drawings G, H, and I, it is engaged between the blades of an advancement forceps in order to immobilize it (drawing J).

Sutures similar to those used in the Reese resection operation are inserted in the muscle central to the forceps, to prevent the retraction of its central freed end before it is sutured to the globe (drawing K). Similar sutures are placed in the peripheral end of the inferior-oblique muscle, the recession forceps are removed, and the cut ends are sutured to the globe. A space of 3 mm. between the two rows of sutures should be allowed (drawing K). No muscle tissue is removed. Following this tying of the sutures the globe is depressed downward for a few moments so that the tissue may as much as possible resume its preoperative relationship.

The external rectus, if it is not to be operated upon further, is reattached to its insertion by interrupted catgut sutures (drawing L). If a resection or an advancement of this muscle is contemplated, it can be done now. The conjunctiva is then closed by interrupted sutures (drawing M).

The advantages of recession of the inferior-oblique muscle from the external-rectus approach are:

1. A second (skin) incision is unneces-

Fig. 1 (Guibor). Recession of the inferior-oblique muscle from the external-rectus approach.

A, An 8-mm. vertical incision, 3 mm. from the external canthus, is made through the conjunctiva. B, Longitudinal fibers of the external rectus are showing through Tenon's capsule. C, The external-rectus muscle is exposed by an incision through Tenon's capsule. This muscle is on the strabismus hook. D, A suture is placed through the external-rectus muscle. E, The external rectus is freed from the globe and retracted by this suture. F, The squint hook approaches the inferior-oblique muscle. Note direction of

sary because in most cases of squint the external rectus is operated upon anyway.

2. The field of operation is more accessible than in the other approaches to the inferior oblique.

3. There is little possibility of tenotomizing the inferior rectus if the test for the inferior-oblique action is made as described.

4. The results can be accurately foretold in most cases, and a recurrence of the overaction of the inferior oblique is unlikely to ensue.

5. Postoperative paralysis of the inferior oblique is less likely to occur than when a myectomy of this muscle is done.

SUMMARY

A procedure for recession of the inferior-oblique muscle from the external-rectus approach is suggested. Drawings

made from photographs of the operation are presented. These illustrate:

1. Incision through the conjunctiva.
2. Exposure of the external rectus.
3. Insertion of sutures in the external rectus.
4. Freeing and retraction of the external rectus.
5. Isolating the inferior oblique on the hook and identification of the muscle.
6. Freeing of the inferior-oblique muscle from the lateral-rectus and inferior-rectus muscles.
7. Grasping the inferior-oblique muscle with the recession forceps midway between the origin and insertion.
8. Insertion of the sutures in the inferior-oblique muscle, its section, and its reattachment to the globe.
9. Reattachment of the external-rectus muscle to the bulb.
10. Closure of the conjunctival incision.

TRANSSCLERAL LACRIMAL-CANALICULUS TRANSPLANTS*

GLEN GREGORY GIBSON, M.D.

Philadelphia

The fact that glaucoma is one of the common causes of blindness and one of the most difficult therapeutic problems encountered by ophthalmologists justifies further research in an attempt to control this destructive disease. In view of the limitations of present-day management of that group of clinical entities which we classify as glaucoma, we are looking forward to the day when an adequate medical regime will entirely replace the surgical treatment of glaucoma. Medical treatment has many obvious advantages over surgical treatment. It seems more rational, and is the type of treatment in which the prospects for successful future advances seem more likely. Until that day when the satisfactory medical treatment has been established, it is still necessary to rely on the surgical approach to this problem in both the clinical and the research fields.

Of the more satisfactory types of operative procedures for the control of ocular hypertension have been those operations which, in order to establish aqueous filtration, utilize uveal epithelium to form a permanent channel through the sclera from the anterior chamber to the subconjunctival tissues. While these types of operations are performed merely to secure symptomatic relief, it has been demonstrated that they are fairly effective in preserving vision in many eyes when performed at a sufficiently early date. In view of the technical disadvantages of all these accepted operations, it is with considerable hesitancy that an even more

complicated and technically difficult procedure is proposed, such as transscleral canaliculus transplants. However, this seemed an interesting field for surgical research, and consequently the following investigation was carried out.

THE PROBLEMS

It is the purpose of this thesis to report a series of experiments which were performed with the immediate objective of investigating the various early steps in the establishment of an epithelial tube through the sclera with the ultimate hope of finding a type of filtration operation that might be an addition to our operative armamentarium in the control of glaucoma. Since an epithelial tract of iris tissue functions satisfactorily in some instances and fails in others, another source of epithelial tissue was sought which would have anatomic and physiologic advantages over the uveal tissue. The tubelike structure of the lacrimal canaliculus seemed to satisfy this requirement. If it could be satisfactorily grafted into the sclera, it might be utilized as a source of epithelial tubing for the establishment of a drainage canal from the anterior chamber through the sclera to the subconjunctival spaces. The six main problems which presented themselves were: (1) Could the canaliculus be satisfactorily dissected from the lids and freed of connective tissue? (2) Could it be placed into the sclera satisfactorily? (3) Could it be maintained in position? (4) If it were maintained there, would it be grafted and remain viable or would it become necrotic? (5) Would the eye tolerate this transplant? (6) If so, would it filter aqueous in the proper amount?

*From the Department of Ophthalmology, Temple University Medical School. Candidate's thesis for membership accepted by the committee on Theses, American Ophthalmological Society, 1942.

PROCEDURE

Problem 1 was solved relatively easily. In the spring of 1938 one eye of each of seven dogs was operated on. Under ether anesthesia the lacrimal punctum of dog 1A was dilated and a lacrimal probe was inserted. A circular incision was made through the conjunctiva around the punctum, about 1 mm. from the probe. Dissection was carried down into the tissue about 3 to 4 mm. on all sides of the probe. When this depth had been reached, the probe was withdrawn slightly and the canaliculus was cut transversely, leaving a collar of canaliculus about 3 mm. long around the probe. The specimen was trimmed of connective tissue, and a satisfactory segment of the lacrimal canaliculus was obtained for transplantation.

Problem 2 was the placing of the graft into the sclera. A keratome incision was made through the sclera into the anterior chamber, but it was found technically impossible to place the graft into the sclera, and the first eye was lost. This difficulty, however, suggested the necessity of inserting an obturator into the lumen of the canaliculus. Consequently, segments of metal lacrimal stylets, about 3 mm. long, were fashioned, and at the second operation the canaliculus was placed around the stylets quite satisfactorily. When the stylet containing the canaliculus was introduced into the keratome incision, the cornea was so displaced in dog 2A that it became obvious that some type of procedure that would remove part of the sclera was necessary to accommodate the graft. Since a keratome incision had been made, the eye of dog 2A was lost for further research. In the third experiment, which was performed on dog 3A, the canaliculus was prepared as previously described. A keratome incision was made in the sclera, about 2 mm. from the limbus. Then, with a

Berens scleral punch, a 1-mm. segment was taken from the anterior lip of the scleral incision. The graft with the metal obturator was inserted, and it fitted well into the scleral opening. The conjunctiva was closed over the metal obturator and the graft. Two days later the obturator had slipped out of position and the eye was lost. The fourth experiment, which was performed on dog 4A, was similar to the foregoing experiment, except that an L-shaped stylet was used in an attempt to keep the graft from slipping. This seemed to work somewhat better, but a severe incarceration of the iris occurred, which suggested the necessity of combining an iridectomy with the transplantation in order to prevent the development of an iris synechia. In the fifth experiment, on dog 5A, an angled stylet was introduced through the Berens punch wound after an iridectomy had been performed. On the third postoperative day the wound became infected and the transplant sloughed out. The same result was met with in the next two operations on dogs 6A and 7A. All the operations in series A were failures, and the conclusion was drawn that the stylet was too great a foreign body and proved an unsatisfactory obturator. None of the material from these experiments was adequate for microscopic study. The second step—namely, that of placing the transplant into the sclera—was not feasible, and the work was discontinued for two-and-one-half years, as the opportunity for further research was not available until the fall of 1941, at which time a second series of operations was performed. The animals in this series were termed B.

In September, 1941, this B series of operations was begun. Ten operations on nine eyes of six dogs were performed. It was recognized that a method to create intracanalicular pressure all along

the canaliculus when it was placed in the sclera was necessary. This problem was similar to that in skin grafting, in which one of the paramount requisites is uniform pressure over the graft; it differed from skin grafting, however, in that the pressure had to be applied to the 360 de-

accommodate the canaliculus graft. The canaliculus was then removed from the salt solution. A long no. 0 catgut suture was threaded through the canaliculus, and then turned around and passed back and forth through the canaliculus seven times until it was no longer possible to

CILIARY PROCESS

Fig. 1 (Gibson). Dog 3, series B (left eye). Metal obturator. One week postoperative. Section shows canaliculus close to internal

ANTERIOR CHAMBER

scleral surface, and the canaliculus epithelium is continuous with the epithelium of the anterior part of the ciliary processes.

grees of the internal circumference of the canaliculus. Since the metal obturator had apparently failed in the previous series of cases, the necessity for a softer and absorbable obturator was recognized, and catgut was selected as a possible material.

Accordingly, on September 15, 1941, dog 1 of series B was operated upon under intravenous veterinary nembutal, 4 c.c. being injected according to dosage for the body weight of the dog. The canaliculus was prepared according to the method described in Series A, and placed in physiologic salt solution. A large conjunctival flap was dissected, and a keratome incision was made 2 mm. from the limbus, and about 4 mm. long, passing into the anterior chamber. An iridectomy was performed. With a Berens scleral punch a 1-mm. button was removed from the anterior lip of the keratome incision to

pass further strands through the lumen. Close to each end of the canaliculus a loop of catgut was tied around the strands of catgut as they protruded from the lumen of the canaliculus, and both ends were securely tied. Next the strands which passed through the lumen were cut off close to the knots. Thus the implant consisted of a segment of canaliculus, about 3 mm. in length, through the lumen of which passed seven strands of catgut, which in turn were tightly tied at each end so that they formed a unified obturator. This implant was then inserted into the scleral opening made by the Berens punch. With a little manipulation it slipped snugly into the opening and seemed quite secure. The conjunctival flap was sutured back in place over the implant. The knot on the inner end of the implant could be seen in the anterior chamber, and the knot on the outer end

made a slight protrusion under the conjunctival flap. This solved problem 2; namely, whether the canaliculus could be satisfactorily placed in the sclera. On the third postoperative day the dog died an anesthetic death, never having regained consciousness. The eye was im-

exactly the same manner as was the right eye of dog 1B. The graft fitted snugly into the opening which had been prepared for it. The dog recovered from the anesthesia. Atropine was applied to the eye daily as it was in all subsequent experiments. One week later the eye was

Fig. 2 (Gibson). Dog 6, series B (right eye). Non-obturator technique. One week postoperative. Longitudinal section of canaliculus. The canaliculus is misdirected here, due to a technical error in operation.

mediately removed, placed in formalin, and sent to the pathology department for microscopic study.

The microscopic slides from this dog failed to show the operative field. Due to a technical error in the preparation of the sections no microscopic evidence of an operation having been performed was discernible. It is most probable that additional sections from this eye and others in which the operative field was not located would have been fruitful, but for technical reasons this was not done.

On September 22, 1941, dog 2 of series B was operated on in a similar manner, but before the operation was completed the dog died an anesthetic death. The operation was completed, but no study was made or conclusion drawn from this experiment, and there was no material for microscopic study.

On September 29, 1941, the right eye of dog 3 of series B was operated on in

examined and was found to be in excellent clinical condition. There was only slight conjunctival reaction, restricted to the operative field, such as one sees after a trephining operation. The cornea appeared to be normal. Two weeks later the reaction had almost completely subsided, and the catgut was not visible in the anterior chamber. Five weeks after the transplant this dog was again anesthetized with 5 c.c. of intravenous nembutal, and the conjunctival flap was again elevated in order that the operative field might be explored. The area of the canaliculus was located, and it was found to be covered with a very thin membrane of tissue on the external surface of the sclera. Gentle stroking of the membrane with a spatula caused it to rupture, and the aqueous was lost although the sclera was not opened. This suggested that the aqueous was coming through the canaliculus but was being retarded by this thin

membrane. The membrane was so thin that it seems probable that if the aqueous had been under pressure as in glaucoma, it would easily have permeated the membrane. This solved problem 3, showing that the canaliculus could be maintained in position. The conjunctival flap was then resutured.

Ten days later the eye was exam-

and the catgut was not visible in the anterior chamber. Three weeks after operation the eye was enucleated for microscopic study. Due to a technical error in the preparation of the sections, the field of operation was not visible in the microscopic specimens.

On October 13, 1941, the left eye of dog 5 of series B was operated on. The

Fig. 3 (Gibson). Dog 3, series B (right eye). Catgut technique. Eight weeks post-operative. This section shows canaliculus growing half way through sclera. The large open white area is not the anterior chamber, but a deep tear made in the sclera in preparation. The smaller opening is only part of the lumen cut obliquely. The lumen remains patent after eight weeks.

ined, when the reaction was found to have subsided and the anterior chamber had formed. A hypodermic needle was introduced through the cornea into the anterior chamber, and sterile salt solution was forced in under pressure, through a syringe, to determine if the canal was patent, but no subconjunctival bulging over the area of the transplant could be demonstrated. One week later this eye was enucleated and sent to the laboratory for study. The pathologic material from this eye was properly located, and revealed the canaliculus with open lumen transplanted deep in the sclera.

On October 6, 1941, the left eye of dog 4 of series B was operated on in a similar manner. Eight strands of no. 0 catgut were drawn through the lumen of the canaliculus and placed in the sclera, as previously described. Ten days later the eye was in excellent clinical condition,

canaliculus was excised, a conjunctival flap was made, and a keratome incision was made 2 mm. behind the limbus. An iridectomy was done, and a scleral punch with the Berens instrument was made. Eight or nine strands of catgut were threaded through the canaliculus, and the transplant was inserted into the punch wound. It snapped firmly into position, and the inner knot was visible in the anterior chamber; the conjunctiva was closed with a single suture. Examination two weeks later revealed that the knot had absorbed from the anterior chamber; the eye was soft, and a large pool of subconjunctival aqueous was present. One week later, or three weeks after this operation, sterile salt solution was forced under pressure into the anterior chamber, but no evidence of fluid exchange from the anterior chamber to the subconjunctival space was demonstrated.

On December 1, 1941, in the absence of other experimental material, and since this same eye looked as good as though it had not been operated upon, it was decided to do a second canalizing operation of a different type on this same eye. A subconjunctival flap was dissected temporal to the area of the first operation. A keratome incision was made, and a second iridectomy was done. At this time

sclera down through the depth of the wound. Pressure was to be obtained by the tightly drawn sutures, thus firmly opposing the two margins of the wound. The conjunctiva was closed. Two weeks later, after the two operations, the eye was in excellent clinical condition and was enucleated for study.

The microscopic sections revealed the transplanted canaliculus. In one area the

Fig. 4 (Gibson). Dog 4, series B (right eye). Non-obturator technique. Two weeks postoperative. Canaliculus growing in center of sclera. The lumen is partly open and partly collapsed. This experiment shows that the transplant can be placed without an obturator, but the lumen remains open better in the catgut technique.

it was our impression that the previous technique had not been satisfactory, and another type of operation was performed. No catgut or metal obturator was employed and no Berens punch procedure was used. The canaliculus was sutured into the incision in the sclera. Two silk sutures were placed in the corneal margin of the incision and then passed through the side of the canaliculus without perforating the lumen; the sutures were then passed through the posterior part of the keratome incision, and the canaliculus, without an obturator, was inserted in the keratome incision. It fit snugly in place. The sutures were tied, and the canaliculus was in a very satisfactory position. It was hoped that the raw external surfaces of the canaliculus would graft to the surface of the incised

lumen was cut so as to show that it still contained degenerating catgut. The epithelial cells were partly necrotic in certain sections, and the graft, although present, did not appear to be so successful as it was in some of the others. In some sections a partial section of the epithelium could be seen growing quite normally. The area where the nonobturator technique was used was not positively located in the microscopic section.

On November 17, 1941, the left eye of dog 3 of series B was operated on. The flap, the incision, the iridectomy, and the Berens punch opening were all made in the routine manner. However, a metal (brass alloy) obturator, consisting of 3 mm. of a lacrimal stylet, was used. This stylet was fashioned so as to have two flanges on one end; these protruded lat-

erally about 1 mm. on each side, so that the obturator could not slip into the anterior chamber. The stylet was placed in the lumen of the canaliculus. It fitted snugly into the punch opening with the canaliculus. The conjunctiva was closed. Examination one week later revealed that

showed the opening of the canaliculus within the eyeball. The epithelium of the canaliculus could be seen growing over the internal margins of the scleral wound, and the epithelium of the canaliculus appeared to be growing over to join the epithelium of the ciliary body. While

Fig. 5. (Gibson). Dog 5, series B (right eye). Catgut technique. Three weeks postoperative. Section shows fair growth of epithelium with some necrosis. Around the canaliculus there is a zone of tissue composed of new granulation tissue, new round cells, edema, some pericanalicular connective tissue, and some new and active blood vessels.

there was a severe reaction, that the cornea was very hazy in the upper third, and that the obturator had sloughed out of the place where it had been inserted and was almost ready to drop out of the eye. Salt solution injected into the anterior chamber did not come out under the conjunctiva, and one week after operation the eye was enucleated and sent for pathologic study.

The microscopic material from this eye consisted of 12 slides arranged in incomplete serial sections. The first five of these showed great thickening of the episcleral tissue due to young granulation-tissue proliferation combined with intense cellular infiltration and edema. The sixth slide showed the canaliculus grafted and viable in the sclera, with a somewhat mild cellular reaction around the canaliculus. In one section the transplanted epithelium

these sections do not reveal an undoubted opening, they do show that the epithelial graft takes all the way through the sclera, down to and continuous with the ciliary epithelium. Following along the sclera in the other sections, the healthy transplanted epithelial tubing can be followed all along the depth of the sclera to the surface. The epithelium averages about seven cells in thickness. The lumen is patent all along the tube; the surface of the epithelium is smooth, and the cells are viable. The basement membrane is intact, and adherent in its complete circumference in all the sections. This experiment answered problem 4, in that the graft would take and remain viable and not become necrotic. This and all the other eyes in this series B answered problem 5, that the dog's eyes would tolerate the operation.

On November 24, 1941, the right eye of dog 4 of series B was operated on. Two silk sutures were inserted in the anterior margin of the scleral incision, and passed one on either side of the resected canaliculus; then the sutures were put through the posterior margin of the scleral incision. The Berens punch was not used in this operation. The canaliculus was inserted into the scleral incision, so that one end extended into the anterior chamber and one end was left protruding under the conjunctiva. No metal nor catgut obturator was used in this experiment. There was very little reaction, and the eye was in excellent condition when, two weeks later, this eye was removed and sent for pathologic examination.

Examination of the serial sections from the right eye of dog 4B revealed that the area of operative interference was accurately located. In some of the sections it was possible to locate a portion of the transplanted canaliculus. The lumen was adequately open. The epithelium was intact, the cells were normal in appearance, and there were about 10 cells from lumen to basement membrane. The epithelium was neatly adherent to the sclera in its entire circumference and there was no evidence of operative activity in the sclera immediately adjacent to the canaliculus. There was slight infiltration of round cells, and there were quite a few more capillaries in the pericanalicular zone than are seen in normal sclera. Following the sections from the middle toward the external and internal surface of the sclera, it was found that the canaliculus became progressively smaller until, at either extremity, it appeared that the lumen of the canaliculus was almost obliterated.

About 2 or 3 mm. from the transplant there was a low-grade, well-circumscribed abscess that extended about half-way through the sclera. In its low-grade appearance this abscess resembled an early

tubercle. While it extended along the transplant, it did not involve the transplant. It appeared as if it would become absorbed. There were no clinical signs of inflammation.

Although this experiment was satisfactory from the standpoint of grafting, the canaliculus did not reach either surface of the sclera in the sections which we obtained.

On November 10, 1941, the right eye of dog 5 of series B was operated on. The steps of this operation were as follows: (1) The canaliculus was prepared. (2) A conjunctival flap was made. (3) A 3-mm. keratome incision was made and the Berens punch was used. (4) The opening in the conjunctival flap was sutured, as it was inadvertently button-holed. (5) Eleven strands of catgut were threaded through the canaliculus. (6) The Berens punch opening was twice enlarged, as the implant was larger than usual. (7) The implant fitted snugly in place, and the conjunctiva was closed.

Three weeks later the eye was in excellent condition, and it was enucleated and sent to the laboratory for microscopic study.

The microscopic report of the right eye of dog 5B revealed that the transplanted canaliculus was viable, with open lumen growing in the sclera. The lumen was completely open and contained a transudate and some fragments of catgut. The epithelial surface was relatively smooth, and appeared to be about five or six cells in depth. A few of the cells appeared to be sloughing off the surface. The basement membrane was in complete contact with the surrounding connective tissue from the lid, and this in turn was in close contact with the adjacent sclera in its entire circumference. There was excellent capillarity and evidence of circulation in the transplant all the way up to the epithelium. The scleral fibers coursing

around the transplant were normal except for the slight curving displacement caused by the transplant. In none of the sections was there any evidence of scar tissue due to the operation. The transplant gave the appearance of normal structure in its normal locus. Some of the sections showed areas where small fragments of the mucous membrane had sloughed away, and the cells appeared less viable than in some of the sections which were surrounded with less connective tissue. In this section neither of the ends of the canaliculus was located.

On December 8, 1941, the right eye of dog 6 of series B was operated on. The procedure in this case was the usual flap, iridectomy, and keratome incision. The incision was enlarged laterally with scissors, and an iridectomy was performed. The canaliculus was prepared and sutured in place in the sclera with two sutures, as previously described, but the position was not satisfactory. The wound was closed. Convalescence was uneventful, and one week later the eye was removed and sent to the laboratory for study.

The sections from this dog's eyes show an excellent "take" of the epithelial tube. The tube can be demonstrated to extend from one surface of the sclera to a point quite deep in the sclera. The section is cut so as to give a longitudinal section of the transplanted canaliculus. The lumen is well opened. In some of the sections the catgut sutures which were used in this case can be seen coursing into the margins of the canal. The epithelium, which is healthy in most places, can be followed for a considerable distance traversing the sclera. Due to difficulty in getting it properly inserted at the time of operation, the direction of the canal is not correct, but the graft is very successful and it can be seen to be growing into the surrounding sclera. Although the specimen is only one

week old, it is unquestionably growing quite solidly into the sclera along the entire course of the tube.

Summary of procedure. Seven eyes of seven dogs were operated on in series A. While the operations were all failures, invaluable lessons were learned and applied to advantage in series B.

In series B the operation was performed on nine eyes of six dogs. For various technical reasons four of these specimens were of no value. Of the remaining five eyes, which came to fairly satisfactory microscopic study, all showed evidence of success. In two the evidence of success was not marked. In three it seemed quite satisfactory. In none of the dogs' eyes was there clinical or microscopic evidence which suggested that an entirely patent channel had been established. However, our efforts in this regard were not so complete as they might have been.

DISCUSSION

The encouraging features of this experiment were: (1) The relative simplicity of the procedure. (2) The minimal clinical reaction and excellent postoperative appearance of all the eyes that had been operated on (exception: metal obturator case). (3) The success of the "take" of the graft. As the numerous microscopic slides were studied, one was constantly struck with the healthy appearance and completeness of the "take" of the epithelium. (4) The patency of the lumen. (5) The absence of untoward microscopic evidence of scleral reaction and scar formation.

The microscopic studies of the fate of the two ends of the canaliculus left something to be desired. This was partly due to the extreme difficulty of locating the ends of the tube in the microscopic studies. Problem 6—namely, Would the

canaliculus filter aqueous?—remained unanswered because we did not have chronic intraocular hypertension in the dogs' eyes and our attempts to force aqueous through the canal were somewhat incomplete.

OBJECTIONS

There are many objections to this procedure, some of which are obvious and probably many others to which attention must be called. The first of these is the technical difficulty inherent in the preparation and the fit and maintenance of the graft. Such technical difficulties have been fairly well overcome.

Clinical difficulties may present themselves, such as the presence of hypotony, ectasia, phthisis, and late infection, which must be considered as possible pitfalls, and which, if they do occur, may be disastrous or may be overcome by modifications of the technique. None of these, however, was encountered in the dogs' eyes.

There are biologic objections that may be encountered clinically and that have to do with the activity of the epithelial cells in the anterior chamber. Unsettled are the problems of their growth, necrosis, obstruction, or opening of the ends of the tube.

Optical objections also are to be considered, such as refractive errors, and the effects on the lens and iris.

One of the most important objections is bacteriologic. Although it was gratifying to see that none of the eyes showed clinical signs of infection, and only one eye exhibited microscopic evidence of infection, yet the series is too small to warrant great enthusiasm in this regard. The procedure used in the operating room was designed merely to prevent the introduction of new organisms into the eye. Hands were scrubbed carefully, and the instruments received the usual preopera-

tive care. The eyes were merely irrigated with boric acid, and they were carefully draped as in routine eye surgery. The canaliculi, which obviously were contaminated, were not subjected to anything stronger than physiologic salt solution. This was done in order to determine if intraocular implant infection was likely to occur, and in series B this did not occur. These experiments were all terminated short of the time required for late infection, although one eye was followed uneventfully for eight weeks before it was removed.

CLINICAL APPLICATION

All the well-known rules and limitations which are inherent in animal experimentation and their application to clinical cases unquestionably apply in these experiments. Due cognizance is taken of the probable undue enthusiasm following the partial success of these intrascleral-canalculus transplants in animals, and the improbability of ultimate clinical success in crossing the gap between animal experiment and clinical application.

SIGNIFICANCE

After consideration of the more obvious objections and limitations, after the clinical observations on the dogs' eyes, and after studying the many microscopic slides in this experiment, the conclusion was reached that the procedure was sufficiently promising to warrant a clinical trial. Accordingly, a patient with glaucoma who had little vision to lose was selected for clinical trial.

CASE REPORT

On May 15, 1939, F. D., aged 57 years, colored, came to the Temple University Hospital Eye Clinic for ocular treatment. He stated that one year previously he had had an operation on each eye performed elsewhere. His chief complaint was of

failing vision. There was no history of ocular pain. Examination revealed that his vision, with glasses, was 6/60 in each eye. The external appearance of the eyes was normal except for an iridectomy at the 12-o'clock position in each eye. The visual fields were concentrically contracted to less than 10 degrees. The ocular tension was 43 mm. Hg (Schiötz) in the right eye and 18 mm. in the left. The media were clear. Fundus examination revealed bilateral glaucomatous cupping of the disc. The diagnosis was advanced post-operative chronic simple glaucoma.

Since there was so little residual function of the optic nerve, further surgical treatment at that time was considered inadvisable. During the next two-and-one-half years various combinations and concentrations of pilocarpine, eserine, and epinephrine bitartrate were used. The tension, however, remained elevated all this time, regardless of which medication was used, and in spite of medical treatment there was a progressive loss of vision in each eye. In June, 1941, the patient's vision was O.D., light perception; O.S., 1/60. In December, 1941, vision in the right eye was nil and in the left eye it was 1/60. The tension in the left eye was usually between 36 and 57 mm. Hg.

Since the right eye was blind, and for over two years was known to have chronic hypertension, and because iridectomy had previously been performed, this eye was selected as ideal for experiment. Any reduction of tension which might result could not be attributed to the iridectomy. Furthermore, if this eye, which had so long been damaged, could tolerate the transplant, it seemed fair to conclude that the procedure might be applicable to eyes with much less advanced changes. On January 14, 1942, the right eye was operated on. At this time the intraocular pressure was 40 mm. Hg (Schiötz).

OPERATION

Under general anesthesia (sodium pentothal injected intravenously), 6 mm. of the upper right canaliculus was dissected from the upper lid and freed of connective tissue. It was then immersed in 1:500 metaphen for 10 minutes. A conjunctival flap was dissected. Next the canaliculus was dilated with a puncta dilator, at which time, due to overdistention, it was torn for about one-half its length. Five strands of no. 0 catgut were threaded through the lumen with considerable effort. A keratome incision 3 mm. long was made through the sclera, 2 mm. behind the limbus. The incision was enlarged laterally with scissors. A segment was punched from the anterior margin of the incision, but the obliquity of the incision prevented a complete punch wound from being made. The canaliculus was placed into the wound. The knot could be seen resting on the anterior lens capsule. This was owing to the fact that the canaliculus segment was too long. The conjunctiva was closed. Technically, it was much less difficult to perform this operation on the human eye than it had been to do so on the dogs' eyes.

POSTOPERATIVE COURSE

The first two postoperative days were uneventful. On the third day, due to pressure of the catgut knot, a round spot of corneal infiltration developed at the 12-o'clock position. On the fifth postoperative day a localized grayish exudate formed in the anterior chamber beneath the area of corneal infiltration, and this was continuous with the anterior lens capsule. On the sixth postoperative day there was a rather severe reaction, and a definite hypopyon formed in the lower part of the anterior chamber and lasted six days. It was doubtful if this repre-

sented actual intraocular infection or merely iris irritation. Sulfathiazole was administered by mouth on the third postoperative day, and on the fifth day, a course of typhoid vaccine was begun. These measures controlled the untoward effects of the operation. On the tenth postoperative day the tension was 0 and on the sixteenth day it was 3 mm. Hg. The reaction, while still fairly marked, was receding, the eye was comfortable, and the progress was quite satisfactory. There was a white mass of tissue at the external end of the transplant which seemed to be due to necrosis of the excessive amount of canaliculus outside the sclera. This mass of necrotic tissue was absorbed in about four days. On the eighteenth postoperative day the tension was 14 mm. On the twenty-fourth postoperative day the tension was 17 mm. There was a visible area of localized elevation of the conjunctiva similar to that seen after trephining. The reaction had subsided. The one untoward effect of the procedure was partial opacity in the upper fourth of the lens. It would appear that the graft was successful, and that the canaliculus was filtering aqueous in this case. It seems most probable, how-

ever, that the opening will eventually close.

PROGRESS NOTE

About six weeks after completion of this report the subconjunctival pool of aqueous on the patient's eye disappeared and the tension returned to its preoperative level. The operative field was explored, and it was found that the external end of the canaliculus was closed by subconjunctival scar tissue. A transscleral lacrimal transplant was subsequently performed on this man's other eye and this case will be reported later.

CONCLUSION

In this one case the eye was able to tolerate this operation, and at least a marked reduction in tension was produced during the first three weeks of the convalescence. Further clinical trial seems justifiable, and numerous technical improvements are to be made.

Although it is possible that there have been reports of previous canaliculus transplants, I am unaware of them. This work is still in the experimental stages, and we are not in position to recommend it as a clinical procedure.

255 South Seventeenth Street.

TEST CHARTS REPRESENTING A VARIETY OF VISUAL TASKS*

MATTHEW LUCKIESH, D.Sc., D.E.

Cleveland

To ophthalmologists and others engaged in examining eyes and in servicing them with corrective lenses, visual acuity is a very important visual function. Likewise, common test charts, consisting of "black" characters on a "white" background serve very well their specialized purpose. However, both visual acuity and the common test chart have often led eye specialists into misinterpretations and erroneous conclusions in connection with visual tasks encountered in everyday seeing. Common test charts of high brightness contrast between the test characters and their background fall far short of representing the countless critical visual tasks performed daily for long periods throughout civilized activities.¹

The common test charts, and even more refined test objects, have been designed for determining visual acuity as specifically defined for a limiting condition. Certainly they were not intended for a more extensive purpose without appropriate considerations. Nevertheless, eye specialists have often misinterpreted and extended without justification the significance of determinations arising therefrom. For example, many statements have been made to the effect that visual acuity for so-called normal eyes reaches a maximum at about 10 foot-candles. At best this statement is incomplete and in a practical sense is meaningless. Sometimes such statements are extended to include defective eyes. In such cases it has been stated that for defective eyes to attain maximal visual acuity, the level of illumination must be greater than 10 foot-

candles or even as much as 100 foot-candles. Here again the statement assumes black objects on a white background, which obviously is a special case.

Much confusion has arisen from such statements chiefly because the conclusions are based upon typical test charts or test objects of maximal contrast between the (black) characters and their (white) background and ignore the fact that most visual tasks involve brightness contrasts far below maximal and reflection factors far below that of so-called white surfaces.

At this point it is essential to distinguish between foot-candles and brightness and to recognize the enormous influence of brightness contrast (between object and background) upon visual acuity. Brightness is a combined result of the reflection factor of a surface and of the foot-candles illuminating it. For example, a *foot-lambert* of brightness is produced by one *foot-candle* of illumination if the surface diffusely reflects *all* the incident light; that is, if the surface has a reflection factor of 100 percent. Some extremely pure white powders approach this value. So-called white papers have reflection factors of 75 to 85 percent. The diffuse reflection factors of most materials vary from those high values to a few percent for dark cloth or so-called black ink to less than 1 percent for black velvet.

It should be obvious that visual acuity as commonly defined is determined by an arbitrary set of conditions that cannot possibly be representative of the infinite variety of combinations of the factors involved. As commonly defined, visual acuity is the reciprocal of the threshold size of a critical detail; that is,

* From the Lighting Research Laboratory, General Electric Company.

of the smallest size of a critical detail involving a "black" object on a "white" background. However, threshold size increases enormously as the brightness contrast decreases. Likewise the influence of level of illumination greatly increases as the brightness contrast decreases. Furthermore, the level of illumination necessary for distinguishing a critical detail of a given reflection factor increases as the reflection factor of the background decreases.

These relationships can be readily illustrated by measurements of "visual acuity" made with test charts on which the same characters are used but with different reflection factors of characters and backgrounds. The A.M.A. test chart was carefully photographed and prints were made with nonglossy photographic paper to exact size. By means of different ex-

had white backgrounds with a reflection factor of 82.5 percent. The reflection factor of the standard letters of the A.M.A. test chart varied from the usual "black" of chart 1 to a medium gray whose reflection factor was 65 percent in the case of chart 2, to a light gray whose reflection factor was 76.5 percent in the case of chart 3. It would aid in visualizing to note again in table 1 the difference between the reflection factor of the letters and that of the white background in each of these cases and also the effect of these differences upon brightness contrast. This effect is also shown by the following simple formulae.² When the surfaces of the background and of the letters diffusely reflect light and the test chart is uniformly illuminated, brightness contrast, expressed in percent, is equal to

$$100 \times \frac{\text{Brightness of background} - \text{Brightness of letters}}{\text{Brightness of background}}$$

posures of the print and of different degrees of "fogging" of the background a variety of test charts was readily produced. Four of these were selected for

In such a case diffuse reflection factor (DRF) may be substituted for brightness. Therefore, brightness contrast expressed in percent is equal to

$$100 \times \frac{\text{DRF of background} - \text{DRF of letters}}{\text{DRF of background}}$$

the present purpose and the descriptions and essential data are briefly presented in table 1.

It will be noted that charts 1, 2, and 3

In the less common case when the object is brighter than the background, background and object are interchanged in the foregoing formulae.

TABLE 1

DATA PERTAINING TO FOUR TEST CHARTS. REFLECTION FACTORS AND BRIGHTNESS CONTRASTS ARE EXPRESSED IN PERCENT. THE TEST CHARACTERS WERE IDENTICAL IN SIZE AND FORM ON ALL THE TEST CHARTS

Test Chart	Diffuse Reflection Factor		Brightness Contrast
	Background	Letters	
No. 1 Black letters on white background	82.5	2.8	96.5
No. 2 Medium-gray letters on white background	82.5	65.0	21.3
No. 3 Light-gray letters on white background	82.5	76.5	7.3
No. 4 Black letters on dark-gray background	3.3	2.6	21.1

Charts 1, 2, and 3 might be further visualized by placing strips of black, medium-gray, and light-gray papers, cloths, or threads on a white paper or cloth.

Chart 4 has a very dark-gray background, instead of a white one, and the letters are the usual "black." The brightness contrast between the letters and background is practically identical to that

rected to normal by means of eyeglasses. The charts were of standard size and were viewed at the standard distance of 20 feet.

The object of this paper is to illustrate certain principles that are commonly overlooked in interpreting measurements of visual acuity with the usual test charts into the much more complex realm of see-

Fig. 1 (Luckiesh). Showing the level of illumination (foot-candles) necessary to make various lines on four different test charts barely readable at the standard distance of 20 feet. Chart no. 1 was the equivalent of the A.M.A. test chart. The other test charts are more representative of many visual tasks encountered in everyday seeing. The data represent the average from 20 subjects possessing so-called normal vision or corrected to normal by means of eyeglasses.

of chart 2. However, there is a great difference in brightness between charts 2 and 4 for the same level of illumination. In fact, to make these two charts identical as visual tasks, the level of illumination must be much greater on chart 4 than on chart 2. This is illustrated in figure 1, which is a plot of average results obtained with a group of 20 subjects possessing so-called normal vision or cor-

ing. Therefore, such a group of subjects is adequate for the purpose.

Various interesting facts are revealed by figure 1. It is seen that, on the average, line 3 of chart 4 was barely distinguishable under an illumination of 84 foot-candles. The same line on chart 2 could be barely read under an illumination of about 12 foot-candles.

On the standard chart 1, line 1 (repre-

senting a visual efficiency of 100 percent by A.M.A. rating or 20/20 by Snellen rating) could be barely read under an illumination somewhat less than 10 foot-candles. However, on the average, line 1 on charts 2 and 4 could be barely read under an illumination of 525 foot-candles, or more than 50 times the level of illumination required in the case of the

jects. However, a more important point is that "visual acuity" in everyday seeing is greatly affected by reflection factor, brightness, and brightness contrast. In cases of very low reflection factors and very low brightness contrasts involved in many visual tasks, visual acuity, in a practical sense, does not reach a maximum until levels of illumination of hun-

Fig. 2 (Luckiesh). Data obtained with the four different test charts under four different levels of illumination. The shaded area represents the "spread" in each case among the 20 subjects possessing normal vision or corrected to normal with eyeglasses. The bold horizontal line in each shaded area represents the average line in each case which is barely readable by all subjects. The white area in each case represents the lines on each test chart which could be read by all subjects under each of the four levels of illumination, respectively.

standard chart 1. Line 1 on chart 3 could not be read under any level of illumination, even thousands of foot-candles.

The lessons taught by figure 1 should be obvious. Certain categorical statements or generalizations that have been made are indefensible and even ridiculous. The statement that visual acuity, determined by black characters on a white background, reaches a maximum at about 10 foot-candles is based upon the common black-on-white test chart. This is by no means true when determined by more refined devices, for visual acuity continues to increase up to and beyond 100 foot-candles for black-on-white test ob-

jects and even thousands of foot-candles are reached.

Imagine, for example, garment workers sewing with black thread on dark goods. The ordinary test chart, within its limitations, is suitable for determining refractive errors of their eyes, for prescribing certain corrections in eyeglasses, and for measuring visual efficiency in its limited fundamental sense. However, if the eye specialist is to extend his analyses to the task the garment workers perform and to comments on lighting and to specification of foot-candles, he is inadequately equipped with data. He would span a great portion of the gap if he used a test chart such as chart 4. Immediately he

would find that, on the average, under an illumination of 10 foot-candles, lines 1 to 6 on chart 4 are not readable as indicated in figure 1. From a practical viewpoint he might properly conclude that the average visual efficiency was 75 percent or vision was 20/50. He would also find that more light is the only practical aid available and would have to use higher levels of illumination if lines 1 to 6 are to be readable.

If the eye specialist carried the test far enough with this universally essential factor, he would find that 100 foot-candles increased "visual acuity" and "visual efficiency" for the garment worker engaged in his everyday tasks. He would also find that by increasing the level of illumination this worker would be progressively aided. Eventually he would reach several hundred foot-candles, such as are available at some windows or on some porches in the daytime. Continuing upward, he would reach 1,000 foot-candles and more. If the eye specialist were examining the group used in the present work he would find that on chart 4 he would have to have 525 foot-candles on the average for all the subjects to reach a "visual efficiency" of 100 percent.

In figure 2 are presented the "spreads" of the determinations made with these four test charts under four levels of illumination. It is emphasized that the 20 subjects had so-called normal vision or their vision had been corrected to normal with the use of eyeglasses. The shaded area in each case represents the spread for the 20 subjects, and the horizontal bold line in this shaded area represents the average of all subjects. Some of the subjects could read line 1 of the standard chart under 1 foot-candle and nearly all of them could do so under 12 foot-candles. The latter level of illumination produced a brightness of the white background on chart 1 (also on charts 2

and 3) of approximately 10 foot-lamberts. Under an illumination of 120 foot-candles, some of the subjects could read line 1 on chart 2, but only 10 percent of the subjects could read this line on chart 4. Under an illumination of 525 foot-candles, all could read line 1 on chart 2, none could read line 1 on chart 3, and only 70 percent of the subjects could barely read line 1 on chart 4. Actually, the illumination necessary to barely read line 1 on chart 4 varied from about 125 foot-candles for one subject to approximately 1,000 foot-candles for two subjects. Only 30 percent could read this line under a level of illumination of 525 foot-candles, which was the average "threshold" illumination for the entire group.

It should be noted that the diffuse reflection factor of the background of chart 4 being 3.3 percent, the brightness of this background when illuminated by 525 foot-candles is 0.033 times 525 or about 17 foot-lamberts. Only 21 foot-candles is necessary to produce this same brightness of the white background of chart 1. In addition to the need for 25 times more foot-candles to make the background of chart 4 equal in brightness to that of chart 1, still more light is necessary in the former case to make up for the relatively low brightness contrast. As a consequence, line 1 on chart 4 is only barely readable on the average under 525 foot-candles, whereas on chart 1 it is barely readable under somewhat less than 10 foot-candles for this group of subjects with so-called normal vision. Incidentally, from adequate knowledge of the visual characteristics of this group it is sufficiently representative for the purposes of this investigation.

Again imagine a group of garment workers sewing with black thread on dark cloth. The foregoing illumination values are for "barely seeing." No factor of safety is included for easier seeing. In addition, no allowance is made for old

eyes or defective eyes. No allowance is made for the fact that the percentage of ocular defectiveness is high among garment workers. Surveys have shown as high as 78 percent of garment workers have eye defects.³ All these facts provide food for thought besides revealing the gross faultiness of statements carelessly made as to the adequacy of 10 or 20 foot-candles.

From the data presented one may consider numerous visual tasks. The choice of garment workers is of no particular significance. They were used merely to direct attention to a specific case. Illumination has been emphasized because there is no other means of increasing "visual acuity" and "visual efficiency" to a high level for the countless tasks not represented by black-on-white test charts. The eye specialist will do well to realize that his experience, tools, techniques, and interpretations in connection with his work on eyes and knowledge of vision have limitations when he considers the visual tasks in the world of seeing.

SUMMARY

The author has no quarrel with the test charts in common use nor with the overwhelming importance assigned to visual acuity for the eye specialist's use in his specific practice. However, visual acuity and the common black-on-white test charts have gross limitations when applied to everyday seeing.

Contrast sensitivity, or the ability to see differences in brightness, is a very important factor in seeing. At night, on the highway, for example, it far outweighs visual acuity in importance.⁴ In everyday visual tasks at ordinary levels

of illumination, brightness contrast or the difference in brightness between an object and its background, has a very great influence upon threshold size, and therefore, upon visual acuity.

The literature contains many misinterpretations and erroneous statements pertaining to necessary or desirable levels of illumination, owing to the inadequate basis provided by considerations of visual acuity based upon black-on-white test charts and test objects. This has led to misunderstandings and in some cases to unfair as well as unsound attacks upon specifications of foot-candles. It is tempting to quote some of these statements which in the light of adequate knowledge are ridiculous. However, this would serve no essential purpose that the data in this paper do not adequately fulfill.

The visual tasks that are being performed by millions of persons for long hours daily are not represented even remotely by the common black-on-white test charts, which are examples of the easiest tasks of critical seeing. Test charts such as numbers 2, 3, and 4 are representative of many critical tasks of seeing, and the four charts at least span much of the range of everyday visual tasks. It is seen that levels of illumination of 100 to 1,000 foot-candles are necessary for barely seeing line 1, which represents a visual efficiency of 100 percent or 20/20 vision.

The author acknowledges the valuable work of A. A. Eastman, T. J. Borsch, G. P. Kerr, and T. Knowles in making and calibrating the test charts and in obtaining the data.

NOTES, CASES, INSTRUMENTS

A CASE OF ACUTE METASTATIC DACRYOADENITIS

EMANUEL ROSEN, CAPT. (MC), A.U.S.

Camp Pickett, Virginia

That acute dacryoadenitis is a rarity may be readily appreciated when one realizes that men like Arlt and Schirmer stated that they had never seen a case of

Fig. 1 (Rosen). Acute metastatic dacryoadenitis.

this disease in the acute phase. The recent excellent review of this condition by Richardson¹ suggested that it is so rare that all cases should be reported.

S. B., aged 20 years, was admitted as a patient at the Station Hospital on December 15, 1942, suffering from a mild acute, suppurative, nonvenereal penile lesion of undetermined cause. It was associated with an acute, right, inguinal lymphadenitis. The patient had noticed the penile lesion about three weeks prior to admission to the genito-urinary service and stated that he had been exposed one week earlier. Pertinent in his past history was the fact that he had had an attack of gonorrheal urethritis in 1940 and in 1941. He denied the existence of any previous penile lesion. The physical examination was negative except for "multiple irregular ulcers in the coronary sulcus on and around the frenulum, and a hard, painful 'bubo' in the right groin." Saline dressings and sulfathiazole 5 percent (powder)

were ordered for the penile lesion and sulfathiazole was given internally.

Three negative dark-field examinations were secured and negative Wassermann and Kahn tests were reported. The Frei test after 72 hours was reported as negative. On December 21, 1942, the urologic service made the following notation: "At the present this appears to be a non-specific lesion due to trauma incurred at the time of intercourse."

On December 20, 1942, the right eye became red, edematous, and swollen. The involvement was suspected of being an early conjunctivitis and was treated accordingly. The eye continued slowly to become worse notwithstanding frequent boric-acid applications, and it was noted that the condition appeared much worse in the 24 hours just prior to the requested ophthalmologic consultation.

The patient recalled that during the attack of "gonorrhea" in 1941 he had had a similar involvement of his right eye, it having been inflamed, red, tender, and swollen at its lateral aspect. He had received no medication for this ocular condition, yet these symptoms disappeared in 8 or 10 days. He did not recall that any secretion had been present and did not believe that there was any degree of pain at any time during the course of the ocular disturbance.

On December 26, 1942, the patient was referred to the eye clinic because of the increase in pain, tearing, redness, and secretion in the right eye. The eye and lid had become tense and painful in the upper temporal portion. Upon this initial examination the outstanding features included a peculiar violaceous congestion of the temporal half of the bulbar conjunctiva of the right eye together with an edema of the outer third of the upper lid,

producing a characteristic *italic letter-s curve* with the long axis of the "s" in a horizontal meridian. When the temporal third of the lid was raised upward, a mild chemosis of the palpebral conjunctiva was evident. This had not extended to the bulbar conjunctiva. As the lid was pulled up the lacrimal gland readily prolapsed into view. It was extremely injected, thickened, cyanotic, and glassy in appearance (fig. 1). In extent it ran well on toward the center of the lid, gradually tapering as it continued in this direction. When the examiner's index finger was placed along the lateral portion of the external orbital margin it was quite evident that the normal sharp edge of this area had become rounded off by a more or less firm swelling. This area was not extremely tender, although eversion of the lid produced excessive pain. Many subconjunctival hemorrhages were present in the upper outer portion of the bulbar conjunctiva.

In 24 hours the acute dacryoadenitis had become progressively worse and now involved the orbital as well as the palpebral portion of the lacrimal gland. This gland showed an increased tenderness and a brawny induration and it prolapsed into the cul-de-sac. The right eye showed some exophthalmos. In looking to the right and up diplopia occurred, due to restricted motion of the eye in this direction. The upper temporal quadrant was the area most involved, but some of the congestion had now spread to the lower temporal bulbar conjunctiva. There was slight preauricular adenitis along with temperature elevation of 1.5 degrees. Smears and cultures of conjunctival secretion, blood count, blood chemistry, and sedimentation rate revealed no significant findings. The urine specimen showed many white blood cells.

This acute phase persisted for three days without any improvement, and a bi-

opsy was contemplated for diagnostic purposes. On December 29th, there was definite improvement for the first time, the gland having become smaller and the congestion appearing less intense. On December 31, 1942, it was noted that the gland was rapidly shrinking and that there was evidence of fluid substance in the gland, which now resembled a large sac. The normal sharp border of the supraorbital margin had returned, and the intense violaceous congestion had begun to disappear.

On January 3, 1943, the eye showed a great improvement, very little swelling, redness, and pain being present. The penile and glandular lesions had all healed by this time, and the patient was discharged from the Hospital on January 7, 1943. Daily conjunctival smears failed to show any gonococci. No acute conjunctivitis was present at any time and the lacrimal gland was not involved by any direct extension. At no time was there any involvement of the cornea, anterior chamber, iris, lens, vitreous, or retina. The diplopia when the eyes were up and right was present for a period of four days only. The vision in each eye was 20/20 and remained so throughout the period of observation. The originally described conjunctival hemorrhagic areas were completely absorbed at the end of two weeks, at which time most of the redness and swelling had disappeared.

It is interesting to note that in Richardson's case there were repeated negative cultures and smears for gonococci, but when a complement fixation test was performed the reaction was reported as positive. This, however, could not be performed in the present case. It has also been pointed out that this condition shows a tendency toward recurrence. Although no positive etiologic factor was ascertained and although gonorrhea was not established as the cause of this complica-

tion it is well known that the condition involving the lacrimal gland may arise from a source where the organism has remained dormant, such as in the very vascular portion of the prostate. This would appear to be particularly true in cases where a previous urethritis had existed and had not been treated adequately. The

fact that in this case there is evidence of recurrence of the dacryoadenitis and that a similar previous attack had occurred during an acute urethritis would strongly make one suspect a related etiologic factor.

CONGENITAL CYST OF THE OPTIC NERVE*

S. A. AGATSTON, M.D.
New York

Miss B. K., aged 19 years, appeared at Dr. Bernard Samuels's Clinic at the New York Eye and Ear Infirmary on December 3, 1942. She was apparently a normal, healthy individual, of average size and intelligence. She complained of slight symptoms of eyestrain.

Her vision was 20/20 in the right eye and 20/20 in the left eye. There was no external abnormality and no muscle imbalance. Her refractive error was, O.D. -0.25D.sph. \approx +0.50D. cyl. ax. 180°; O.S. +0.50D. cyl. ax. 180°.

The fundus of the left eye was perfectly normal. That of the right eye, however, showed a cystic mass $1\frac{1}{2}$ discs in diameter, extending from the limit of the upper third of the disc down and out below the disc. This cyst was somewhat oval in shape with 6D. elevation, and was moderately translucent. The surface of the cyst wall was covered by small blood vessels. The retinal vessels behind the cyst appeared to be normal,

entirely unaffected by the presence of the cyst (plate 3, fig. 1). The blind spot of the left eye was normal, as was also the visual field. The blind spot of the right eye was four times larger than normal, and the visual field was definitely cut on the temporal side to 55 degrees for a 3-mm. white test object on the perimeter (fig. 2).

The family history was negative except for the fact that the mother had a right convergent squint. Her fundus was normal. A brother, aged 10 years, also showed a normal fundus.

In February, 1943, I saw another patient, a boy, S. B., aged 16 years, whose fundus disclosed a flat connective-tissue cystic area similar to the one reported, over the disc of the left eye. This area did not appear quite so definitely cystic. I have not as yet obtained a photograph of the fundus.

The embryonal hyaloid canal, known as the canal of Cloquet, is the basis for many anomalous pictures.

These were well classified by DeBeck¹ in 1890. His classification refers to 12 different phases. These are as follows: 1. Shred of tissue on the optic nerve. 2. Membrane on the disc. 3. Cystic remains on the disc. 4. Massive connective tissue on the disc. 5. Rudimentary strand at-

* Presented at the meeting of the Ophthalmologic Section of the New York Academy of Medicine, May 17, 1943.

tached to the disc. 6. Strand on the disc and posterior capsule of the lens. 7. Strand from the disc to the lens. 8. Similar strand containing blood. 9. Strand

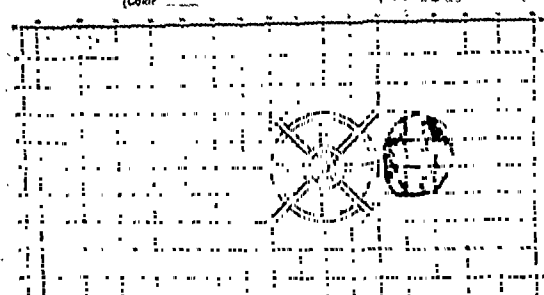

In 1906, Parsons³ in his "Pathology of the eye," mentions a case which showed a large blindspot but no contraction of the visual field.

attached to the lens alone. 10. Posterior capsular cataract. 11. Striae on the posterior lens capsule. 12. Persistent canal, without remnant of the vessels.

This is a quite comprehensive list although many other familiar variations are seen.

Cystic prepapillary remains have also been reported by Randall² in 1888.

Hunter W. Scarlett⁴ reported a case in 1922, and Yudkin⁵ reported one in 1926.

In 1939, Levitt and Lloyd⁶ reported a prepapillary cyst, containing a moving vascular loop. The blindspot was markedly enlarged and the visual field was also somewhat contracted.

A RATIONAL BASIS FOR CROSS-CYLINDER TESTS

JOSEPH I. PASCAL, M.D.

New York

The how and why of cross-cylinder tests can be more easily understood by a study of the diffusion spots that make up the retinal image in an astigmatic eye than in any other way. It can be shown that when the astigmatism is changed to equally mixed astigmatism, the effect of flipping the cross cylinder is to change the *size* of the retinal diffusion spots without changing their form. Images made up of larger or smaller diffusion spots of the same *shape* can be easily compared as to clearness, the image made up of smaller diffusion spots naturally being the clearer.

To clarify the basis of the procedure it would be well to redefine a few of the terms used. "Fogging" means to make an eye myopic by means of a plus sphere if it was not "fogged" or myopic to start with. In the presence of astigmatism, simple or compound, "full fogging" means making both principal meridians myopic. "Half fogging" means making one principal meridian emmetropic, the other myopic. "Unfogging" may be used to mean leaving the examined eye hyperopic or making it so by means of minus spheres. In the presence of astigmatism, simple or compound, "full unfogging" implies both meridians being hyperopic, "half unfogging" implies that one meridian has been made emmetropic, the other hyperopic. "Meridionally balanced" or simply "balanced" means that, where astigmatism is present, one meridian has been made myopic, the other hyperopic; in other words, the astigmatism has been changed to mixed astigmatism.

Using these terms in the sense outlined we can say that cross-cylinder tests made while the examined eye is "fogged"

(fully or half), or "unfogged" (fully or half) are difficult, often unreliable, and sometimes even misleading. But if the tests are made after the eye has been "balanced," as nearly as possible evenly balanced—that is, as strongly hyperopic in one meridian as it is myopic in the other—then the tests are more effective, more definite, and free from misleading clues. The reason for this is that only when the eye is balanced, do the two positions of the cross cylinder produce diffusion spots that are readily comparable. These spots are diffusion *circles* (in a physiologic not a geometric sense) of *different sizes*. Whereas when cross-cylinder tests are made on an eye that has not been previously "balanced" the diffusion spots resulting from the two positions of the cross cylinder differ in *size* and *shape*, leading to difficulties in comparison and sometimes even to misinterpretation. I think even Dr. Crisp's new ingenious test for axis described in this Journal for June, 1943, would work more smoothly if the eye or photographic camera was first balanced rather than half-fogged.

Possibly the long-delayed realization of this cardinal principle in cross-cylinder tests was due to the way the imperfect focusing in an astigmatic eye was diagrammatically presented. The usual method was by diagrams showing the position of the two focal lines and their shifting back and forth by means of spheres and/or cylinders. If the real entity that enters into the formation of the retinal images—namely, the retinal diffusion spot—is studied, the principle and importance of "meridional balancing" at once becomes apparent.¹

Williamson-Noble has amplified the procedure and in a series of striking photographs has shown the principles involved as no other method can. In order to maintain "meridional balance," Wil-

Williamson-Noble makes a most excellent suggestion; namely, to use the duochrome test, better known here as the bichrome test.² This paper should be read by every eye physician. Another amplification of the subject, showing how the "balanced"

condition can be maintained throughout the test by means of *correcting* cross cylinders as well as *testing* cross cylinders, has been published by the writer.³

AN ILLUMINATED RETRACTOR FOR EYE OPERATIONS ESPE- CIALY FOR DETACHMENT OF THE RETINA*

CONRAD BERENS, M.D.
New York

Because of the need for good illumination in operations for detachment of the retina, orbital operations, and operations on the inferior-oblique muscle, an

illuminated retractor has been devised. This may be inserted into a flashlight handle (fig. 1) or attached to a cord and rheostat. The retractor is of plastic material, the handle is 51 mm. long, and the tip 18 mm long by 8 mm. in diameter. The tip forms an angle of 165 degrees with the handle. The tip is concavo-convex to facilitate the manipulation of electrolysis and diathermy tips and needles in the hollowed-out part.

The tip is slightly frosted to project the light onto the scleral surface.

35 East Seventieth Street.

A COLOR FILTER FOR RETINAL PHOTOGRAPHY*

FERDINAND L. P. KOCH, M.D.
New York

It has become necessary for many who use the carbon-arc models of the Zeiss-Nordenson retinal cameras for color delineation of the eyegrounds, to decelerate their activities in this respect because of the relative scarcity of daylight Kodachrome film in the bantam pack (K828), although those who work with the later nitra-lamp instruments still are able to

* This study was aided by a grant from the Ophthalmological Foundation, Inc. Made by V. Mueller & Company, Chicago, Illinois.

* From the Departments of Ophthalmology of the College of Medicine, New York University and Bellevue Hospital.

obtain the artificial-light Kodachrome (K828A). The latter, perhaps, does not afford quite so true a coloration as does the former but it is adequate. Similar, reasonably true values may be attained with carbon-arc illumination and artificial-light color film if one resorts to the expediency of using an accessory filter.

This may be done inexpensively with the use of a Type A, C4-Harrison filter, which may still be purchased on the open market. One may obtain it in various sizes according to whether the operator

of the camera wishes to place the filter in front of the objective lens at the patient's end of the photographic tube or to have it reground for placement in the small, removable filter frame that is received into a slot in the stationary vertical tube situated between the shutter housing and the prism-placement grouping just to the rear of the source of illumination. It is not necessary with this device to alter one's amperage and exposure tables.

780 Park Avenue.

SOCIETY PROCEEDINGS

EDITED BY DR. DONALD J. LYLE

CHICAGO OPHTHALMOLOGICAL SOCIETY

November 16, 1942

DR. LOUIS G. HOFFMAN, *president*

CLINICAL MEETING

(Presented by the Department of Ophthalmology, University of Illinois)

BILATERAL OPTIC-NERVE ATROPHY (JUVENILE TABOPARESIS)

DR. MARTHA RUBIN FOLK presented the case of A. K., a 16-year-old boy who, when first seen on September 4, 1912, complained of blurring of vision for a period of four years. Vision was 0.1 in each eye. The pupils were unequal in size, the right measuring 4 mm. and the left 3.5 mm.; the left pupil reacted sluggishly to light. Upon ophthalmoscopic examination, the optic papilla was seen to be pale, with clear margins and narrowing of the vessels. Perimetric study showed concentric contraction of 20 degrees of both visual fields to form and color. Homat-

ropine refraction revealed an error of R.E. +2.75D. sph. \approx +0.25D. cyl. ax. 180°, vision 0.1; L.E. +2.50D. sph., vision 0.1.

The blood Wassermann reaction was 4+, and 1+ Kahn. Colloidal gold curve of the spinal fluid showed 5321555300.

Diagnosis made by the Department of Neurology was that of central-nervous-system syphilis with the possibility of early taboparesis. Antisyphilitic therapy was instituted.

CONGENITAL ABSENCE OF LEFT PUNCTA

DR. ROOSEVELT BROOKS presented H. B., a man, aged 22 years, who was referred by the Selective Service Board for correction of tearing in the left eye.

On examination, the right eye was found to be entirely normal. The left eye was watery but the conjunctiva was not injected. Complete absence of the puncta above and below was found. No opening of the lacrimal sac could be found in the nose and it was assumed that the sac was also absent.

Operation: An incision was made in the skin slightly nasalward to the position of the lacrimal sac and the nasal bone was exposed, through which an opening was made into the nose. A double silkworm gut suture was passed from the lid margin at the site of the puncta into the wound, then into the nose. The lower end of the suture was brought out of the nose and fastened to the cheek. One week later a small silver tube was threaded over the silkworm suture into the nose and the sutures were then removed. The end of the tube in the nose was bent downward, the upper end was bent nasalward over the bridge of the nose and fastened by adhesive tape.

It was hoped that by this procedure epithelization would occur. No record of a similar case was found in the literature.

PEMPHIGUS OF THE CONJUNCTIVA

DR. CARL APPLE reported the case of a woman, aged 71 years, who had a purulent discharge from the right eye for two years, and from the left eye for six months. Following bronchitis two years ago, she had continued sore throat, choking spells with hemoptysis, and blisters on the tongue, which bled at times; there were ulcers on the palate, tongue, pharynx, and epiglottis. Dysphagia had been present for a year and a half.

X ray of the lungs showed negative findings; sputum was negative for acid-fast bacilli; smears were negative for fusiform bacilli or spirochetes; blood Wassermann test was negative. The blood count showed 4,500,000 red cells; 11,500 white cells: 41 percent lymphocytes, 48 percent neutrophils, 4 percent eosinophils, and 7 percent mononuclears.

Pemphigus of the conjunctiva usually occurs with lesions of the mucous membranes of the mouth, throat, and nose; rarely in conjunction with eruptions upon

the skin. Bullae are exceptional; denuded areas are found in the conjunctiva, which rupture from pressure of the exudate beneath and result in scarring, with final constriction and disappearance of the retrotarsal folds and adhesion of the lids to the bulb. Ulcers of the cornea may occur in the late stages.

DERMATOLOGIC LESIONS ABOUT THE EYES

DR. OLIVER S. ORMSBY read a paper on this subject which was published in this Journal (August, 1943).

Discussion. Dr. Robert Von der Heydt inquired about riboflavin deficiency, and whether this treatment was given in cases of acne rosacea with involvement of the nose and "butterfly" lesions on the cheeks. With reference to the eye changes in lupus erythematosus, this condition involves the eye but little in comparison with the skin, and these patients are almost exclusively seen and treated by dermatologists.

Dr. Sanford Gifford asked whether the Macht test is considered to be of diagnostic value in pemphigus. In 8 or 10 cases the tests had been reported as highly toxic. Dr. Ormsby had mentioned the deep lesions in the cornea caused by pemphigus, but in his own experience, while there is scarring, the lesions are very superficial; the bullae rupture and there remains but a little erosion, with no hypopyon. It seems that the epithelium is chiefly affected, and is replaced by thick horny epithelium that covers the cornea.

Dr. Ormsby, in closing, said with reference to the effect of light in producing lesions or causing exacerbation of symptoms in rosacea and pellagra, there is a definite influence on the last-named disease. In Peoria and other state institutions some years ago, while pellagra was being investigated, fenestrated gloves were used on many patients and the hands were exposed to the sun. In the

open areas of the gloves pellagrous symptoms developed very actively. On the other hand, many patients were seen who developed lesions in areas not coming in direct contact with the sun's rays. One elderly patient who had been bedridden for years was in a comparatively dark room; the pellagra was well developed and the cutaneous lesions were very active. It is not believed that the actinic rays produced pellagra but that they are effective in bringing out the lesions in a sensitized skin. Goldberg, who did the remarkable work on food deficiencies in pellagra, stated that during winter months (when patients in the South have little pellagra-preventive foods) vitamin deficiencies occur that cause an acute outbreak in the spring when the sun's rays become more potent. Most of the cases occur from March to June. The part that hematoporphyrin plays in sensitizing the skin in these patients is debatable. No particular effect has been observed of the sun's rays on rosacea.

Ocular tuberculosis associated with tuberculosis of the skin is quite common; this was not discussed here for lack of time. Lupus erythematosus of the conjunctiva and lids was mentioned because this condition has been recognized only for a few years; if attention is called to it more cases will be detected. As it can be cleared up with treatment, a proper diagnosis is valuable to the patient.

Concerning the effects of riboflavin in rosacea, very little effect has been seen on the cutaneous lesions, but a decided effect has been noted on the ocular lesions associated with rosacea.

The description of ocular pemphigus was made as a composite of a large number of cases recorded all over the world by dermatologists and ophthalmologists, particularly the latter. In the early stages the vesicles are always superficial and usually leave without trace. Later, when

the disease attacks deeper tissues of the eye and sclerotic changes occur, vesicles no longer develop, although they may be found on other mucous membranes. The Macht test is used as a confirmatory finding; a positive test is valuable in confirming the diagnosis of pemphigus. It is a phytopharmacologic method of testing the toxicity of the blood serum for plant protoplasm. In about 90 percent of patients with pemphigus the blood serum shows greater toxicity than that of normal persons.

As most cases of contact dermatitis are of allergic or hypersensitive nature, and as sodium thiosulfate is the most valuable drug in overcoming sensitization, we have found it of great value in this type of dermatitis. It is used in dosage of one gram intravenously three times a week for a week or 10 days. Two excellent local applications consist of the aqua calcis lotion and a naftalan ointment. The first preparation contains sodium baborate 10 grams, powdered zinc oxide 15 grams, powdered starch 15 grams, liquor calcis 120 grams, and aqua rosa q.s. ad 240 grams. A very efficient ointment consists of naftalan 6 grams, powdered zinc oxide 15 grams, powdered starch 15 grams, and petrolatum to make 60 grams. It has not been found necessary or advisable to use phenol in the aqua-calcis lotion.

THE USE OF PRISMS IN OPHTHALMOLOGY

DR. GEORGE P. GUIBOR presented a paper on this subject which appeared in this Journal (August, 1943).

Discussion. Dr. Richard Gamble said that he had had the opportunity of watching Dr. Guibor develop his ideas and put them to use. The theories are fascinating and the results are good. The most valuable suggestions he made are the explanation of overaction of the inferior oblique muscle by synkinesis, the use of prisms, base out, undercorrecting the deviation

in convergent concomitant squint, and the use of prisms, base out, for external-rectus paralysis.

His explanation of the reason for overaction of the inferior-oblique muscle is the only one that seems reasonable. It is usually not possible to demonstrate paralysis of the superior rectus of the opposite eye to one's satisfaction. Another important point is the fact that overaction of the inferior-oblique muscle is extremely common in children but is very seldom seen in adults. This would not be true if it were due to paralysis of the superior rectus of the other eye.

In regard to the use of prisms, base out, undercorrecting the deviation in convergent concomitant squint, one likes to think of the first page in Traquair's book on "Perimetry," in which he refers to the visual field as a "hill of vision in a sea of blindness." In this hill the peak corresponds to the fixation point, the hill slopes off gradually on each side of the peak for about 10 degrees, then slopes off rapidly. The use of prisms, base out, undercorrecting the deviation would be an attempt to make the image fall on the side of this hill, and the eye should then move out sufficiently to have the image fall on the fixation point. If this is so, why did Dr. Guibor not order prisms correcting all the deviation less 10 degrees, instead of correcting much less? It is disappointing that he finds that the use of prisms in this manner is not effective in cases of abnormal retinal correspondence. Would Dr. Guibor make a more definite statement concerning the value of prisms in cases of alternating convergent squint? are they less effective than in cases of monocular squint?

With reference to the use of strong prisms, base out, in cases of paralysis of the external-rectus muscle, he was not so enthusiastic as the essayist. It seems he is doing very little more with these un-

sightly lenses than the patient does by merely turning his head toward the side of the paralyzed muscle. The important point is whether or not there is contracture of the internal-rectus muscle. If that develops before the paralysis recovers it will take more than prisms, base out, to relieve it.

Dr. George P. Guibor, in closing, said that motor defects are always undercorrected with prisms because one is unable to determine the amount of spasticity present. Likewise, it is easier to add more prism to a deviation that is not improving than to remove prism from a patient who is using full correction.

Dr. Gamble is correct in his criticism of the use of prisms in treating parietic deviation, especially so when these deviations are associated with severe suppression and contracture of the opponent muscle. However, in partial defects not associated with contracture, prisms are of considerable value.

Robert Von der Heydt.

SAINT LOUIS OPHTHALMIC SOCIETY

November 27, 1942

DR. LESLIE DREWS, *president*

DENDRITIC ULCER

DR. F. O. SCHWARTZ read a paper on this subject which was published in this Journal (1943, v. 26, p. 394).

Discussion. Dr. M. H. Post said that he had noticed repeatedly that dendritic ulcers heal rapidly on removal of foci of infection, but he had a feeling, too, that this disease is self-limiting to some extent. He had seen cases in which no foci of infection could be found, in which the lesion resisted all local treatment, but, continuing this same local treatment, something took place in the system, and

the eye suddenly healed very rapidly. He said that he had not had much luck with the thermophore in this type of lesion.

Dr. Post said that Dr. John G. Bellows had issued a word of warning about the use of sulfa drugs in lesions of the cornea. Since the action takes place only in vascularized tissue, there is a tendency for these drugs to induce vascularization of the cornea in the region of the ulceration.

Dr. William Shahan said he had found that local applications of 1-percent silver nitrate used very cautiously, tracing the open branches of the ulcer, make them well in three or four days. Of course, when the cases are protracted he also sent the patient to some rhinologist and then to the family doctor.

Dr. Roy Mason said he would like to ask Dr. Schwartz about his case in which the patient was struck by the limb of a cherry tree. He had had a number of these cases preceded by some sort of trauma. One patient got cement dust in his eyes. In a few days he developed a dendritic ulcer. Did the accident activate it or aggravate it? There are very good textbooks that fail to answer this question, but give the impression that trauma has something to do with dendritic ulcer. He has felt that the condition was not due to trauma but, like Dr. Schwartz, to some virus or toxin. So many cases, however, are preceded by slight trauma.

Another phase of the subject is the use of the sulfa drugs. He has been using sulfathiazole internally in these cases and it seemed to him that the patients have been getting well much faster than before.

Dr. F. O. Schwartz (closing) in answer to Dr. Shahan, said he used the thermophore at 154°F. for one minute.

He had seen a number of cases of dendritic ulcer following injuries; about half a dozen patients had been improved

after the removal of corneal foreign bodies but had returned in a week or 10 days with dendritic ulcer. He was inclined to think the injury paved the way for the development of the ulcer. He had never seen the condition occur in both eyes.

CORNEAL RESECTION FOR DYSTROPHY

DR. VINCENT L. JONES presented the case of a woman, aged 43 years, who had come under his observation in March, 1939. The corrected vision in each eye had been 20/20. Corneal dystrophy or degeneration (without gutter formation) progressed from the periphery until, in February, 1942, the entire cornea in each eye was involved. Vision was limited to the detection of gross motions.

On May 11, 1942, corneal resection was performed, following the method of Meyer Wiener. Erythema doses of X rays were given under the direction of Dr. Sherwood Moore. Healing was uneventful. On August 21st, vision in this eye was 20/400, and on November 25th the vision had improved to 20/200.

Discussion. Dr. William James pointed out the need for better terminology to avoid confusion in discussing corneal conditions. In obscure, so-called dystrophies of the cornea he had used corneal resection in seven cases; four received beneficial results. Yet after about four or six months the cornea became opaque from what he judged was edema. The patients were not benefited permanently at all. To resect down to firm healthy tissue is worthwhile in a great number of cases of scars and erosions of the cornea.

Dr. John Green wished to commend Dr. James on his technique of corneal resection. Dr. James was kind enough to assist him in one case. It was a beautiful demonstration of how the scar tissue can be dissected off in the proper plane of dissection.

In cases of bullae it was quite remarkable how one can get rid of them without regeneration. Not only Ewing but Allen of Chicago showed that the genesis of a bullous keratitis was a disease of Bowman's membrane. If one removes the superficial layers of the cornea including Bowman's membrane a quiet eye will result. Most of his cases had been in blind eyes that could not be removed for some reason.

DR. JAMES M. SHIELDS, *president*

DETACHMENT OF THE RETINA AND CATARACT EXTRACTION

DR. WILLIAM M. BANE presented the case of Mr. R. B., aged 23 years, who was examined by Dr. J. L. Swigert on December 1, 1933. He had symptoms of eye strain with some blurring of vision and a chronic facial eczema. His vision was O.D. 20/20; O.S. 20/50-1. There were also bilateral posterior capsular cataracts, larger in the left eye. Weak lenses were ordered but they did not improve the vision. The fundi were normal. On May 9, 1939, the patient complained of more loss of vision. Examination revealed numerous vitreous floaters in both eyes, also a retinal detachment in the right eye, lower temporal quadrant. This was operated on with immediate good results by Dr. Swigert.

After the first operation there developed what was thought to be a secondary detachment. This was not at the periphery, which seemed healed, but near the center of the original separation. A guarded prognosis was given. A second

operation was performed by Dr. Swigert, with good results and no complications.

Early in 1942, the patient went to the Mayo Clinic for his eczema. A diagnosis of atopic dermatitis was made.

On October 5, 1942, examination revealed a mature cataract in the right eye. This was operated on by Dr. William M. Bane with excellent result. Vision with correction at this time was O.D. 5/20-1; O.S. 5/20-1.

ENDOPHTHALMITIS SECONDARY TO TRAUMA, WITH RECOVERY

DR. RALPH W. DANIELSON presented a 13-year-old boy, who was first seen for refraction in March, 1941, at which time it was found that he was practically emmetropic, each eye, with a vision of 20/15.

He was next seen on June 25, 1942, because on the day before he had been struck in the right eye with a piece of wood.

On examination, it was found that a flat, more or less oblong, sliver of wood was extending through almost the entire thickness of the cornea in a slanting manner. This was removed with considerable difficulty, the attempt being made to avoid pushing the piece of wood into the anterior chamber and injuring the lens. The patient was placed on sulfathiazole, about 0.5 grain per pound of body weight, but in a couple of days it was noted that the cornea was definitely becoming opaque and a hypopyon was developing in the anterior chamber. The sulfathiazole was increased to 0.75 grain per pound of body weight, but, in spite of this, by June 29th, there appeared to be a hopeless endophthalmitis, the cornea showing an increase in opacity and the anterior chamber being so full of hypopyon that the iris could not be seen. It was felt that something drastic would have to be attempted. The sulfathiazole was, therefore, increased to

1 grain per pound of body weight; and a very extensive Saemisch incision was made at the pupillary border, which drained the anterior chamber completely.

This wound was re-opened twice a day for the following week and once a day for several days more.

On July 3d the patient's temperature rose to 103°F., and it was necessary to stop the sulfathiazole. The use of typhoid paratyphoid vaccine was substituted. The eye gradually cleared, leaving an intra-stromal abscess which was opened from the exterior on August 1st and again on August 3, 1942.

On July 24th, the administration of riboflavin, 2 mg., three times a day, was begun. The uncorrected vision at the present time is 20/65, and with a minus 2.50D. sph. \approx +3.50D. cyl. ax. 103°, the vision is 20/15.

This case is presented primarily to demonstrate an eye which, although apparently hopelessly lost, was saved by a combination of sulfathiazole and wide incision of the cornea; (2), the use of riboflavin to increase corneal nutrition; and (3), the remarkable amount of vision now obtained.

Discussion. Dr. Neepser thought phemerol would have been a great help in the early stages of this case. He reported very good results with its use.

SUCCESSFUL RETINAL-DETACHMENT OPERATION IN APHAKIA

DR. RALPH DANIELSON and DR. JOHN LONG presented the case of I. G., a 65-year-old white woman who had had an intracapsular cataract extraction on the left eye in November, 1940. The operation at that time was uneventful and no vitreous was lost. The corrected vision following cataract extraction was 20/20.

On May 21, 1942, a large bullous detachment of the retina, left eye, occurred, and a tear was found in the upper tem-

poral quadrant. This was treated with multiple diathermy punctures. Healing has been satisfactory, the retina having gone back into place; at the present time the corrected vision of the eye is 20/33. The margins of the old tear and the surrounding area of choroidal scarring are plainly seen.

DERMOID CYST OF THE BROW

DR. JOHN LONG presented the case of B. M., a 13-year-old Spanish-American girl. The patient had had a gradually increasing swelling of the lateral angle of the left brow since birth. On November 10th, a cyst, measuring 1.5 cm. in diameter, was excised. This cyst was found to be beneath the orbicularis muscle and not attached to the bone. On opening the cyst, it was seen to contain sebaceous material and numerous tiny hairs. A diagnosis of dermoid cyst was made.

The origin of dermoid cysts was discussed at some length and the theory of Collins and Mayou was mentioned. According to this theory, a dermoid cyst is an inclusion resulting from adhesions between the skin and the suture lines of the skull in early fetal life.

Photographs of the patient and gross and microscopic photographs of the tumor were shown.

FOSTER KENNEDY SYNDROME

DR. W. A. OHMART presented the case of Mrs. D. W. H., aged 28 years, who came to the office on October 22, 1936, complaining of blurred vision. Examination showed an optic atrophy of the left eye. The right eye was apparently normal. Visual acuity at the time was O.D. 20/25; O.S. nil. No lens was of help. The patient stated that Dr. Rudolph Jaeger had operated on her about six years previously for a brain lesion.

In July, 1942, she was again exam-

ined, and a typical Foster Kennedy syndrome was found. A papilledema of about 2 mm. of the disc of the right eye was found. The optic disc of the left eye was atrophic.

She was operated on again by Dr. Rudolph Jaeger.

She again was examined in November, 1942. A peculiar macular lesion was found in the right eye. Optic atrophy was present in the right eye.

For all practical purposes the patient is blind.

Discussion. Dr. Rudolph Jaeger discussed the surgical aspects of the case. Both operations showed the carotid arteries compressing the nerve. Removal of the roof of the optic canal allowed the nerve to be pushed up without pinching against bone.

No enlargement of the pituitary was found at operation.

Dr. W. H. Crisp thought the macular involvement was a capillary breakdown.

Walter A. Ohmart,
Secretary.

MEMPHIS SOCIETY OF OPHTHALMOLOGY AND OTOLARYNGOLOGY

December 8, 1942

DR. D. H. ANTHONY, *presiding*

CONSTANT OCCLUSION IN AMBLYOPIA

DR. E. C. ELLETT reported three cases to illustrate the value of occlusion in the relief of amblyopia. Only constant occlusion was of any value. Anything less was waste of time. The surgical, refractive, and other features of these cases were omitted; they were reported as a few of a good many cases in which the vision was improved by the forced use of the amblyopic eye.

The first patient was L. H., aged six

years, who was seen in April, 1942, with a periodic squint, both eyes turning in under cover, and with an esophoria of 8 degrees. The motion in was stopped by 25-degree prism, base out. Vision in the right eye was 6/15 and J4, and in the left eye 6/6 and J1. On August 4th constant occlusion of the left eye was begun. On October 23d the vision in the right eye had improved to 6/6 slowly, and on November 7th it was 6/6 and J1.

The second patient was A. C., a five-year-old girl, who seen in July, 1942. She had a paresis of the right third nerve, manifested by right hypertropia, ptosis, and a dilated pupil. The vision in the right eye was normal. The vision in the left eye was 6/60. Under constant occlusion of the right eye the vision in the left eye improved to 15/30 in three months, and in five months the vision was 6/6.

The third patient, B. L., a two-year-old boy, was seen in 1938, with convergence of the left eye amounting to 28 degrees. It was not possible to test the vision until a year later, when it was found to be 1/60 in the right eye, and 6/10 in the left eye. Constant occlusion of the left eye was begun in October, 1939, and in January, 1942, the squint was found to be alternating, after which the eyes were occluded alternately. In November, 1942, vision was 6/12 in each eye.

SPASM OF THE CENTRAL RETINAL ARTERY

DR. E. C. ELLETT presented the case of P. R., aged 61 years, who stated that his vision began to fail in April, 1942, the left eye being affected and only at times. The vision was about 5/60 in each eye with glasses. The blood pressure was 126/80. He had had some bad teeth removed and the physical examination otherwise was negative. On the morning he was seen, August 5th, he had four

spells of blurring of vision. He was seen during one of them. Some of the retinal arteries were entirely empty of blood, some showed a broken column. While the eyeground was under observation, the arteries began to fill from the disc end and were soon normal. The time was too short to permit testing the vision and field while the spasms were present, and it was too interesting and unusual a sight to miss the chance to watch it. In September, and again in December, 1942, he reported no further attacks and he has resumed his work as a railroad engineer.

LENS EXTRACTION IN HIGH MYOPIA

DR. E. C. ELLETT reported the case of N. J., a 58-year-old man, who had been under observation for 33 years. He had worn glasses for 15 years prior to his first visit, and his vision was 20/40 in each eye with $-13.00D.$ sph. He gradually developed some myopic changes and a few vitreous opacities, and the vision became worse. In 1937, visible lens changes were noted and they gradually progressed. In July the vision in the right eye was 6/60 with $-18.00D.$ sph. and in the left eye 6/18 with $-11.00D.$ sph. $\approx -5.00D.$ cyl. ax. 30° . In October, a preliminary iridectomy was done in the right eye, and, in November, an intracapsular cataract extraction. He had a slight anterior-chamber hemorrhage on the sixth day but this disappeared in 24 hours. His vision in the right eye was 6/9 with $+2.00D.$ sph.; with $+2.50D.$ sph. added he could read J2. He was greatly pleased with the new lighter glasses, and with the improved vision.

CONGENITAL PTOSIS

DR. RALPH O. RYCHENER reported the case of P. W., aged nine years, who had had a modified Mottais operation performed on the right eye two months previously with resultant overcorrection,

followed by diplopia, lacrimation, and exposure of the cornea, due to incomplete closure of the lids. On September 9, 1942, with the aid of Dr. P. M. Lewis, the tissues of the upper fornix were taken down, the tongue of the superior-rectus muscle isolated and reattached to the insertion of the ocular muscle, and the levator palpebrae muscle was resected for 4 mm. and the stump sutured to the tarsus. Slides were exhibited of the various preoperative stages along with the final result, which was perfect.

RECESSION FOR HYPERPHORIA

DR. RALPH O. RYCHENER reported the case of R. F., an 18-year-old boy, who was rejected by the Navy because, as the examiner expressed it, "his eyes didn't look right" although his visual acuity was normal. There was a left hyperphoria of 28 degrees due to a paresis of the right inferior-oblique muscle. On July 15th, a 5-mm. recession of the left superior rectus was done, with excellent cosmetic result although on September 8th there was still a demonstrable left hyperphoria of 15 degrees. He was accepted by the Navy on September 10th. Slides were exhibited.

LACERATION OF CORNEA AND SCLERA

DR. RALPH O. RYCHENER reported the case of D. A. C., aged 37 years, who was injured two weeks previously when a soft-drink bottle had exploded in his hand, cutting the right upper lid and lacerating the cornea and sclera. The lid was well repaired but there was a 15-mm. laceration of the cornea at the 9-o'clock position extending up and nasally into the sclera, with prolapse of the iris and ciliary body and marked ciliary injection. Visual acuity seemed fair, and it was determined to apply pure trichloroacetic acid to the wound in the hope that a resistant eschar would be formed. After

two weeks the wound was flat and required no further treatment. On December 4, 1942, the visual acuity was 6/60 but was improved to 6/7.5 and J2 with +4.50D. sph. \Rightarrow -13.00D. cyl. axis 100°. A slide was shown.

SYMMETRICAL MUSCLE PARALYSIS IN IDENTICAL TWINS

DR. RALPH O. RYCHENER reported, with color slides, the cases of S. O. and L. O., four-year-old identical twins, whose mother had noticed that one eye failed to move upward in certain positions. In the one this proved to be due to a paralysis or absence of the right inferior oblique; in the other to a similar condition of the left inferior oblique. Binocular vision with the Worth dot test without demonstrable diplopia was present in the primary position. No treatment was advised.

MYASTHENIA GRAVIS

DR. J. WESLEY MCKINNEY presented a case report of W. S., a 65-year-old man, who was first seen in June, 1940. On the first visit the left upper lid began to droop and in about one month the right upper lid also began to droop. At this time there was also weakness of the jaw so that he had to hold the jaw to be able to chew. There was a paralytic ptosis of the upper lid of each eye varying in degree at different times of observation. All the muscles of the face seemed to sag. The jaw jerk was absent. The ocular rotations were normal and there was no diplopia.

The patient had pernicious anemia and it was thought at first that this was the cause of the ptosis. At one of his visits to the office he was given prostigmine methyl sulphate by hypodermic injection. Within 15 minutes the ptosis had disappeared and the facial expression became normal. His condition varied con-

siderably over the next year and a half but for the most part he had been able to control the ptosis and weakness of the facial muscles with prostigmine by mouth. There has been no spread of the weakness to other muscles.

On one occasion he came in for refraction at a time when the lids were drooping so much that most if not all of the pupil in each eye was covered. After the injection of prostigmine the lids became normal and refraction was carried out without difficulty.

ARGYLL ROBERTSON PUPIL, CONGENITAL

DR. J. WESLEY MCKINNEY reported the case of H. S., a 46-year-old man who was seeking relief from presbyopic symptoms. When it was found that his pupils were very small the patient said that they had always been small. He had had thorough physical examinations on various occasions; these were always negative. The eyes were entirely normal except for the fact that the pupils measured less than 1 mm. in diameter in each eye. They were equal in size but did not react to a strong light, but reacted promptly to convergence. The pupils dilated to 3 mm. in each eye a short time after the instillation of paredrine. This eliminated a parasympathetic paralysis as the mechanism of the condition. The patient refused spinal puncture.

SUCCESSFUL RESULT IN OLD RETINAL DETACHMENT

DR. DEXTER J. CLOUGH, II (by invitation) presented the case report of a 10-year-old boy, who was found to have greatly reduced vision in his left eye when examined by school authorities. The boy and his family were previously unaware of this visual defect. A history of trauma at the age of three years, when the child sustained a fractured nose, was elicited.

Vision in the left eye was limited to perception of hand movements at 3 feet. Ophthalmoscopic examination revealed an almost total detachment of the retina with a massive bulging inward from both the temporal and nasal sides. The patient was hospitalized, and after two days of absolute bed rest in the supine position and fixation of the eyes during the waking hours by appliance of pin-point disc spectacles, there was enough regression of the retinal elevation to reveal a small retinal tear in the upper nasal sector just anterior to the equator.

Diathermy operation for the retinal detachment was carried out, with the use of both the Weve surface-diathermy technique and the Walker micropin technique, about the site of the retinal tear localized on the sclera and over the upper hemisphere of the globe between the ora serrata and equator. Subretinal fluid was released through two trephine holes, one over the upper nasal sector and one over the upper temporal sector to correspond to the nasal and temporal bulging of the retina. Postoperatively the retina was found to have completely reattached, and the vision in this eye a month later was 6/24+ with a full field.

It was not known definitely whether the detachment had existed for seven years, that is, from the time of the nose fracture, but it is probable that it had existed for a considerable time. In view of such an unfavorable prognosis, the good result would encourage the operative interference of any retinal detachment regardless of its duration.

GLAUCOMA SECONDARY TO DISCISSION

DR. J. WESLEY MCKINNEY reported the case of F. C., a 56-year-old man, who had had a successful intracapsular cataract extraction in the right eye. When the left eye was operated on, it was found that the capsule was too tight

to be grasped with forceps, which fact necessitated an extracapsular extraction. A moderate amount of cortex was absorbed rapidly, leaving a fairly dense secondary membrane.

The patient returned for discission two months after the operation. By mistake atropine was instilled preoperatively instead of homatropine, giving very wide dilatation of the pupil. The membrane was needled and a large pupillary opening was obtained.

Two hours after the operation the patient complained of pain which became increasingly severe. The eye became stony hard. For three days the pain was intense; the pupil remained dilated, and tension remained high despite the use of eserine, mecholyl, prostigmine, and heat. The pupil began to constrict on the morning of the fourth day and the tension was less. By afternoon the tension was normal. The tension has remained normal for two years, without the use of miotics, and vision was corrected to 20/15.

GUNSHOT WOUND OF THE EYE AND BRAIN

DR. PHIL LEWIS reported the case of H. S., a colored man, aged 28 years, who was admitted to the eye service of John Gaston Hospital on July 5, 1942, because of a gunshot wound of the left eye. He gave a history that a shot gun was fired at him at the distance of about one-half block. Several shot hit him but only one above his shoulders. He entered the Hospital two hours later complaining of pain in the back of his head and loss of vision of his right eye.

Examination on the following day showed that a shot had perforated the center of the lower right eyelid about 3 mm. from the border. There was a round hole in the sclera about 4 mm. from the limbus in the 5-o'clock meridian. The anterior segment of the eye

was normal except for a dilated pupil which did not react to light. The vitreous was full of blood so that the fundus could not be seen. There was no perception of light. X-ray studies were made to determine the position of the shot. Much to our amazement it was found to be in the lower occipital region and all the ventricles of the brain were filled with air.

Two days later the patient's temperature had risen to 100°F., and he complained more of headache. Further X-ray studies showed the amount of air to be about the same. The optic foramen was normal. No fractures of any part of the skull or sinuses were found. The following day, because his neck was stiff, a spinal puncture was ordered and consultation was requested with the neuro-surgical department. Sulfapyridine was given in the amount of 90 grains a day. The patient's temperature rose to 104°F. He became delirious and the interne was unable to do a satisfactory lumbar puncture. The patient was quite ill for about four days and then began to recover rapidly. An X-ray examination of the skull on July 25th showed that the air had been absorbed. He was discharged from the Hospital in good condition except for the loss of vision in the right eye. The blood in the vitreous had absorbed sufficiently to allow the examiner to see that the retina was detached. The eye was totally blind.

The patient was not seen again for almost two months. He then came in with his eye severely inflamed and very painful. Examination showed an iridocyclitis, fresh blood in the anterior chamber, and secondary glaucoma. Enucleation with glass-ball implantation was performed and was followed by an uneventful recovery.

Abstract from the report of the Army Medical Museum was as follows: Scleral

scars at the points of entrance and exit of shot, dislocation and cataract of lens, recent and old organizing hemorrhages, detachment of the retina, which was drawn over toward the scleral scars.

Comment. It is obvious that the bullet must have traversed the eyeball and orbital tissues and passed through the supraorbital fissure. That it did so without injury to the various important structures in this area is remarkable. Even more remarkable is the fact that it caused the ventricles to become filled with air. Just how this occurred is not clear. Probably a posterior ethmoid cell or the sphenoid was opened and the air came from that source. Certainly the ventricles were pierced in some portion. Complete recovery occurred except for the loss of the injured eye.

SEVERE PROCAINE REACTION

DR. PHIL LEWIS reported a case of near fatality presumably from injection of procaine hydrochloride for a minor plastic operation on the eyelids.

Mr. J. D. R., a white man, aged 73 years, was admitted to the John Gaston Hospital on September 18, 1941. He had an old inactive trachoma with a moderate entropion of the lower eyelids. Considerable corneal irritation was present due to trichiasis. Plastic surgery on the lids was to be done first, and extraction of senile cataracts at some later date was contemplated. Routine physical examination was negative. The man was apparently in excellent general condition.

On the morning of September 19th, he was given 3 gr. of nembutal at 7:15 a.m. At 8 a.m. 4-percent cocaine hydrochloride and epinephrine 1:1,000 were dropped into each eye several times (6 drops of cocaine and 3 of epinephrine in each eye). At 8:15 a.m. both lower lids were infiltrated and the sensory nerves blocked by injections of 1-percent pro-

caine hydrochloride with one drop of 1:1,000 epinephrine per cubic centimeter. A total of seven cubic centimeters of procaine was used. An incision splitting the right lower eyelid was begun. Immediately the operation had to be discontinued due to a sudden, alarming change in the patient's condition. He took a few deep, rapid breaths, became extremely cyanotic and stopped breathing. The heart ceased beating. Artificial respiration by rhythmical pressure and relaxation of the chest was started while hypodermic injections were being quickly prepared. Coramine (1 c.c.) was injected into the external jugular vein. Epinephrine hydrochloride 1:1,000 (1 c.c.) was injected directly into the heart. An Emerson Resuscitator, which pumped oxygen rhythmically into the lungs was employed. After 10 minutes had elapsed, during which time there was no sound of cardiac action and he was apparently

dead, his heart began to beat very feebly. From then on his improvement was steady and after 30 minutes more he was returned to bed with instructions for very careful watching. After two days he left the Hospital in good condition. The operation was not performed.

Comment. In the opinion of all who witnessed this near fatality it resulted from procaine sensitivity. It was true that some cocaine was used but the amount was very small and he showed no symptoms until after the procaine injections. Cocaine had been previously used in his eyes without mishap. This man was clinically dead for 10 minutes and his recovery or resurrection was due to the most efficient services rendered by the Hospital staff. The Emerson Resuscitator certainly played an important part in saving this man's life and was therefore recommended as standard equipment in all hospitals.

Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE WAGNER BILL

In the medical profession there are not many minority opinions with regard to the Wagner Bill. The profession as a whole has turned its face against any form of the socialization of medicine. We are all thoroughly convinced that the highest types of medical practice are carried on in the very personal relationship of private physician to his patient. It is therefore argued that anything which destroys this relationship must be bad in its very essence.

The writer is not aware that anywhere in the medical periodical literature of this

country has anything been said even mildly favorable to the Wagner Bill. Yet there is some reason to believe that the Bill voices the purposes of one much higher in authority and influence than Mr. Robert F. Wagner, the Senator from New York. Many of us are convinced that the Bill in its present form cannot pass through Congress. But there are others who believe that, with the very influential backing of the highest in the land in alliance with the trade unions, the Bill may have a good chance for becoming law.

It is not expected that anything here said will play an important part in either

passing or defeating the Bill. Yet if there exist in the medical profession and among our own good friends any substantial differences of opinion as to the Wagner Bill we ought to know everything possible about such points of view.

Let us, for the moment, ignore any vote-catching problems involved, even among Senators and Congressmen, and consider only principles and practical consequences. As bearing upon the attitude of the medical profession, the only carefully prepared documents with which most of us are familiar as dealing with the Bill are severely and even utterly condemnatory. Chief of these is the report of the National Physicians' Committee, an organization financially independent although apparently owing its inception to the American Medical Association, and receiving support from some of the large drug manufacturers. A short summary of the medical provisions of the Bill has also been issued by the American Medical Association's Council on Medical Service and Public Relations.

Only one other organization within the medical profession appears to have made a careful attempt to analyze the provisions of the Wagner Bill. This is the numerically small but professionally rather significant group known as the Committee of Physicians for the Improvement of Medical Care, Inc., whose Secretary is John P. Peters, M.D., of New Haven, Connecticut. It may be recalled that this organization came into existence six or seven years before the organization of the "National Physicians' Committee," with its rather imitative title.

Perhaps the most striking feature of the Wagner Bill is its breath-taking comprehensiveness. It would undertake provision of medical care for a total number of persons estimated at from 100 to 110 million. The item of finance is mentally overwhelming. The Bill as a whole (with

its increase probably from 37 to 62 million in the number of persons registered under the Social Security laws) might involve the collection of the staggering total of 12 billion dollars from employers, employed, and self-employed. (The average annual revenue of the United States Government from all sources during the ten years 1924 to 1933 inclusive was 3½ billion.)

Something like absolute authority under the law would be placed in the hands of the Surgeon General of the United States Public Health Service, although with aid from advisory councils (Social Security Council, and Medical and Hospital Council) which would have important functions with regard to organization and administration. The Surgeon General would apparently have power to establish rates of payment for medical services, to decide to whom physicians might provide services, to approve or disapprove hospitals and clinics, to publish lists of physicians entitled to render services under the law, and to establish qualifications for specialists.

The A.M.A.-sponsored committee (National Physicians' Committee) declares that, if enacted into law, the provisions of the Wagner Bill would "destroy the private practice of medicine in the United States"; that "State Medicine means abject slavery"; and that for the mass of people it involves "medical care through and by physicians who are politically amenable rather than by those with superior abilities and skills," as contrasted with "the practice of medicine under the Christian concept of the sanctity of human personality."

The Committee of Physicians for the Improvement of Medical Care is also strongly critical of the Wagner Bill, although this Committee, we are reminded, has already recorded its approval of a national health program. The Committee

does, however, offer constructive comment as to the faults of the Wagner Bill as applied to such a health program. Perhaps the most vital criticism of the Bill, as presented by this Committee, relates to the enormity of the program, the attempt to conjure such a plan out of thin air, lacking the benefits that might be derived from a slower and more evolutionary procedure, with its gradual accumulation of experience and the step-by-step adjustments rendered possible by trial and error and correction. "In an experiment of such vast proportions as that contemplated by the Bill it would seem wiser and more conducive to the improvement of medical care to cover at the start a smaller proportion of the population."

We are reminded that a bill introduced by Senator Wagner in 1939 proposed a national health program financed by grants-in-aid to states complying with the standards of the Federal Government. Such grant-in-aid would have permitted gradual development and local autonomy under Federal supervision.

It is further suggested that a tax-supported system might be more equitable and economical. Such a system would make it possible to provide care at first for those who were most truly in need, leaving room for such further expansion as experience and expediency might indicate.

Much has been said for and against the principles of States' rights as contrasted with Federal control, in relation to many lines of activity. The adoption of legislative innovations for relatively small units of the population has at least the virtue of limiting the mistakes that may arise in new experiments, and of permitting valuable lessons to be learned as to the manner of carrying out novel ideas. But Senator Wagner, and those associated with him in the present proposals for sweeping social change, appear to have thrown

overboard the spirit of caution embodied in their earlier plan. The Committee of Physicians for the Improvement of Medical Care suggests that the scope of the new proposals might well at first be limited to a lower income, say \$2,000 or \$2,500, as compared with the \$3,000 limit provided in the Bill.

The present Bill's provision that hospital service shall be of the type offered by "ward or other least expensive facilities compatible with the proper care of the patient" seems to suggest that those who have been accustomed to purchasing semi-private or private accommodations in hospitals, or to consulting physicians who have comfortable waiting rooms and well-furnished offices, will have to forego the benefits provided under the Bill unless they are willing to accept services of the sort furnished in a ward or dispensary. Or are such patients to be allowed to spend private funds on these services while economizing on their payments to physicians? The Committee of Physicians for the Improvement of Medical Care suggests that, however handled, this problem opens the way for abuse, whether to the advantage or to the disadvantage of the physician.

There are those who believe that Mr. Wagner's Bill cannot pass into law. Others, including the "National Physicians' Committee," recognize a danger that the Bill may pass in its present form and are determined to do all in their power to prevent such an outcome. In this spirit of opposition and determination they refrain from such constructive criticism as might be supposed to acknowledge the possibility of improving a desperately bad proposal. The Committee of Physicians for the Improvement of Medical Care, on the other hand, acts on the basis that certain parts of the Bill ought to be constructively modified. Particularly this Committee emphasizes the

weakness of the Bill as to provision for group practice in and out of hospitals. "Medicine," says the Committee, "has long since passed the stage in which the individual medical practitioner can provide good medical care as a solitary individual." While the Bill appears to give the Surgeon General the right to contract for group service, the Committee urges (1) that groups of physicians so approved shall be qualified to furnish medical services, (2) that beneficiaries or groups of beneficiaries shall be permitted to select the medical groups from whom they shall receive services, and (3) that approved groups shall have their names published on the lists provided for individual physicians.

As contemplating the event of the passage of the Bill, another constructive criticism is to the effect that the Bill does not fully recognize the proper organization and function of hospitals, and that the proposed rates of payment to hospitals are too small to cover costs of services by laboratory staffs, internes, and residents. Also, "there is no separate provision for the payment of physicians who furnish professional services in the hospital. It seems to be assumed: first that every hospital shall be an 'open' hospital in which each family practitioner cares for his own patients; and second, that laboratory, X ray and consulting services are to be paid for separately." The Committee suggests that "such a system would negate the principle of coöperative group medicine."

The Committee of Physicians for the Improvement of Medical Care offers important suggestions as to the maintenance of outpatient clinics. Since under the proposed law a large proportion of the patients who now attend outpatient clinics would be able to consult their own physicians, these clinics could no longer be

maintained unless organized as centers of group practice under the law. For this purpose the Committee suggests that the Surgeon General should be authorized to make contracts with approved outpatient clinics for certain services and that the remuneration of the physicians should be included in such contracts. The Committee, however, points out that only by means of a well-organized and highly developed outpatient service would it be possible to avoid the wasteful tendency (which has arisen under existing hospital-insurance systems) toward hospitalizing patients for conditions that do not require inpatient facilities.

It appears that first visits are or may be excluded from coverage under the proposed law. This, the Committee of Physicians for the Improvement of Medical Care points out, "violates the principles of preventive medicine," since it acts as a deterrent to the early treatment of disease. It also tends to prolong disability. A proposal to limit laboratory benefits under the Bill is condemned as inimical to the best medical care. These exceptions are intended to prevent abuse of the system, but such an object should be, the Committee suggests, accomplished in other ways.

The same Committee expresses serious concern as to a proposal to recognize under the law a system of "fee-for-service." This practice, the Committee points out, has been found (under insurance systems) to encourage malingering on the part of the patient and unnecessary multiplication of service by the physician. It is stated that British physicians, under the system of National Health Insurance, have expressed their preference for per-capita payments rather than fee-for-service. The latter practice is also ill adapted to preventive medicine.

Personal contact with British physi-

cians seems rather to indicate that the British Panel System is viewed with less disfavor among the general physicians than among specialists. If in the United States there are any appreciably varying degrees of hostility to the proposed extension of socialized medicine, it is to be supposed that here again the degree of hostility will be found greater among specialists than among general practitioners. The practice of specialized medicine may on the whole be assumed to carry certain advantages over the practice of general medicine, as to social and professional status, personal independence, and financial gain.

The subject of specialization, as dealt with in the Wagner Bill, is scarcely mentioned in the report of the National Physicians' Committee. The Committee for the Improvement of Medical Care, however, intimates that the Bill's definition "of specialists and the manner in which they may be employed lacks clarity." The latter Committee objects to the Bill's prescription of "the exclusive utilization of standards and qualifications developed by competent professional agencies" (presumably examining boards). While "the standards and certifications of these agencies could, like any other relevant data, be employed by the Council, . . . their use should not be prescribed in the Bill."

It is noted that in smaller communities some general practitioners will have to perform functions which in larger cities will be conducted by specialists, and that provision must be made for compensating the general practitioner who has acquired proficiency in special fields. It is further objected that, while the Bill provides for consultation with specialists, it does not specifically recognize continuous treatment by specialists. The Bill provides that "the services of specialists shall ordinarily be available only upon the advice

of the general practitioners," but the Committee insists that the patient should be given the greatest possible freedom in the choice of a specialist.

It is to be regretted that such constructive criticism as is afforded by the report of the Committee of Physicians for the Improvement of Medical Care has not found more general access to the profession. There are a number of physicians who agree with the conclusion of the Chicago "Committee on the Cost of Medical Care" that some form of national program for the improvement of medical care is desirable. Many of us now contribute heavily of time and skill, without financial recompense, to various forms of socialized medicine. The profession is also supporting certain schemes for group health insurance. But the more we study the ramifications and complications involved, the more we are led to doubt the wisdom of venturing, without benefit of the lessons to be learned from more partial and gradual change, into the enormous and revolutionary experiment proposed under the Wagner Bill.

W. H. Crisp.

OUR POSTWAR PROBLEM

The ophthalmologic training centers in the United States are facing a real problem in planning how to meet the demands for ophthalmologic education in the immediate postwar period, demands that are even now mounting in an ever-increasing tide. Owing to the curtailment in the resident service by the armed forces and by the procurement agency, there will be a definite gap in the ranks of well-trained younger ophthalmologists, and it will be the duty of the training centers to make that hiatus as small as possible. Consequently, it is the duty, right now, of the

educators to establish plans and means to care for the influx of men that will flood the ophthalmologic training centers, starting with the beginning of demobilization and continuing for at least two or three years.

Apparently, there will be four main classes to be provided for:

A. Recent graduates who have finished their general internship, who may or may not have served in the armed forces, and who wish to specialize in ophthalmology as their life work. This constitutes the group that have in the past composed the regular resident staff and whose training will proceed along established prewar lines.

B. Residents in ophthalmology whose career was interrupted by service with the armed forces before completion of their training.

C. Men who have had from one to two years (or even more) of training in ophthalmology and who, because of absence from that field of work, require a fairly rapid comprehensive refresher course.

D. Practicing ophthalmologists who have been on duty with the armed forces and feel that they require refresher work before returning to civilian practice.

All four of these groups require separate consideration which must be tempered by the realization that the total number will far exceed any aggregation of ophthalmic students in the past. Consequently, plans elaborated by the training centers must take into account the physical limitations of the centers themselves, such as the amount of laboratory and clinical material available for the necessarily individualized instruction that is so essential in ophthalmology.

The regular resident training of group A should proceed as in the prewar period in general. But care must be taken to limit the number of residents to the prewar level, despite the fact that eventually

each institution must increase its quota of residents to provide an adequate supply of ophthalmologists to the country as a whole. However, that increase cannot be made until the immediate postwar training program has been completed.

Group B presents a somewhat more difficult problem. Each institution has the moral obligation to take back into its resident ranks any man whose training at that institution was interrupted for service with the armed forces, and to complete that training, both in time and scope. This will necessitate practically doubling the resident staff without similar increase in physical equipment or clinical material. That will mean that each resident will have direct charge of fewer patients than in the past, but that can be compensated for by insistence upon more thorough and meticulous work in each individual case. That will also mean that each resident will be given somewhat less surgery to perform than in the past, which may not be an unmixed blessing. It will also mean that under closer direction of the educators, each resident will have more study time available and will emerge from the institution with a better knowledge of the basic sciences (particularly pathology) than in the past. These problems are, of course, peculiar to each training center, but with proper advance planning they can be solved for the greater good of ophthalmology.

The next group is numerically rather small, composed of probably not more than 125 to 150 members, and the problems of this group can be solved rather easily by concerted action of the various training centers. There has been circulated among some of the larger centers a plan to establish an intensive three months' course in ophthalmology, somewhat similar to that given in Vienna in the 1920's, and known as the Fuchs course. Such courses, limited to 25 persons, would be

presented at some six or eight of the larger centers where there is adequate teaching personnel. They would start immediately after the cessation of hostilities and be staggered so as to take care of the men as they are demobilized. The course would cover clinical, didactic, and laboratory reviews of the entire subject of ophthalmology. For the more or less individualized clinical instruction, the class would be subdivided into small groups. Needless to say, the course would be open only to men who had completed at least one full year of formalized instruction in ophthalmology and would not constitute a short cut to the practice. In that or some similar way, this comparatively small group of men whose training falls just short of the desired, could be given the necessary instruction that would fit them to start out in civilian practice. For the success of such a plan, coöperation by the Surgeons General of the armed forces is essential, and this has been tentatively promised.

The last group comprises men who have been in the practice of ophthalmology before their entrance into the armed forces and who wish to fill out the gaps in their knowledge. For these, the formal courses that are presented at various centers throughout the country are inadequate. They do not wish to spend two or three weeks listening to lectures on a heterogeneity of subjects without correlation. They need to observe clinical material and receive some didactic instruction in certain subjects in which they feel they are deficient. For them, attendance at an active teaching clinic offers the best solution available at present. Each clinic must be prepared to receive these men on an informal basis and give them the privilege of browsing, for they know what they need.

All this adds up to the fact that ophthalmology has a job to perform in the

near future and the sooner concrete plans are laid, the less confusion there will be when that job plunks itself down into the lap of ophthalmology.

Harry S. Gradle.

THE SHEARD FOUNDATION FOR EDUCATION AND RESEARCH IN VISION

The movement which culminated in the conception of a Foundation for Education and Research in Vision at the Ohio State University had its beginnings with the introduction of the two-years' course in applied optics in the department of physics at the Ohio State University, in 1914. After some years it became obvious that the importance of the work was so great that it warranted four years of training fundamentally devoted to the basic mathematical, physical, and biophysical sciences with their applications in physiological optics, clinical significance, and practical work. It was proposed to set up in the University a department for research in all phases of problems in vision in which there would be postgraduate instruction in the subjects of physiology, physics, ophthalmology, and optometry to students enrolled in the graduate school of the University, with no restrictions other than the necessary educational qualifications.

There were, from the very beginning, *two projects* definitely in mind: (1) The Foundation for Vision, and (2) the School of Optometry. These projects were naturally inclusive in the minds of only those who thought of vision in terms of optometry alone. But in all pamphlets and statements which have been officially issued by the University there has been an attempt, at least, to emphasize the fact that the Foundation is independent of any system of practice and also independent of the School of Optometry, which is a part

of the educational provisions of the University. The Foundation is an undertaking universally applicable to all matters pertaining to vision and has no connections with the School of Optometry other than those which logically arise by reason of the fact that optometry is a subject pertaining to visual science.

It has long been recognized that research in all phases of visual science is proceeding in a number of schools and laboratories with results that justify continuation of the work. The objectives of the studies may be clinical, psychological, physiological, economic, sociological, or commercial. Whatever of good results from these bits of isolated researches should be panned and preserved for application where they can best be employed. A central processing and proving station is required to evaluate the results of such studies as are carried on there and elsewhere, and it is just that purpose that is to be served by the Sheard Foundation. In order that there may be adequately trained teachers in the things of vision, whether they go as teachers or research workers into ophthalmology, optometry, illuminating engineering, visual direction in industry, physico-physiology, psychology, or some other branch of learning, there must be some center possessed of adequate medical and other collegiate departments and a conviction about and interest in matters of vision.

The purposes of the Foundation are:

1. To stimulate research in every way possible insofar as visual problems are concerned, and to give attention in these researches to both matters of theory and of practice.

2. To exercise a leadership in all matters concerning vision of an educational or research character to the end that the Foundation in Vision may contribute the greatest good to the greatest number possible.

3. To provide facilities and contacts with various departments and schools of the University, and to attract outstanding men in some manner interested in vision to spend a sabbatical year or other period of time in study and research.

4. To develop training for those who are concerned in any wise with vision. This, for example, might consist of a single course for illuminating engineers or safety engineers, a course in physiological optics for psychologists, or for optometrists or ophthalmologists.

5. To train those who are to become the teachers and research workers of the future in the fields of ophthalmology, optometry, specialists in industrial visual problems and to carry a limited number of postgraduate students through thesis requirements and to a doctorate degree.

The Foundation will operate under the supervision of a board of directors composed of outstanding men in the fields of education, medicine, industry, and applied optics. The faculty will consist of a number of full-time teachers and investigators, selected lecturers from related schools, and artisans skilled in optical construction. Instruction and research work will be carried on in such subjects as myopia, color vision, dark adaptation, visual standards, accommodation, eye movements, refraction, reading difficulties, orthoptic training, and visual rehabilitation.

The purposes of the Foundation are laudable and the character of its formation and sponsorship unimpeachable. With a competent staff and adequate financial and moral support from medical as well as lay sources it promises to fill the needs so sorely felt at the present time by all groups of professional men who are endeavoring in their own way to relieve distress of sufferers of visual disturbance or to aid by scientific research and application the lessons learned by researches

in applied optics. The Foundation deserves the moral and financial support of the medical profession.

W. L. Benedict.

BOOK NOTICE

THE READABILITY OF CERTAIN TYPE SIZES AND FORMS IN SIGHT-SAVING CLASSES. By Harold J. McNally, Ph.D. Clothbound, 71 pages. Bureau of Publications, Teachers' College, Columbia University. 1943. Price \$1.75.

An estimate of one child in 500 or over 50,000 of the children in this country are partially sighted and require special educational facilities. Many of these children are in sight-saving classes, of which there are 635. These classes represent 227 cities and 31 states. In New York City there are 88 schools with sight-saving classes, enrolling approximately 2,000 pupils. The education of this large a number of children is a sizable and important undertaking. The author of this book has attempted to determine experimentally the best materials for use in these classes.

Reading tests were made on a large group of partially sighted students, using a variety of types. The reading period and light intensity were controlled. Reading speed and eye-blink frequencies were determined.

The results of the study did not permit the conclusion that any one of the experimental types was preferable to any of the others for use in the sight-saving classes.

H. R. Hildreth.

CORRESPONDENCE

AN ERRATUM AND FOLLOW-UP NOTE

February 24, 1944

Editor, American Journal of
Ophthalmology

In reference to an article entitled "Post operative endogenous infection," which I wrote in collaboration with Dr. Daniel Kravitz, on page 170, paragraph 3 (Feb., 1944 issue) it is stated that the patient's vision is 20/10+. This is an error. Vision at the time of writing the paper was but 20/100+, and final vision, about three months later, was 20/50+.

(Signed) Lloyd J. Duest, M.D.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

OCULAR MOVEMENTS

Verhoeff, F. H. Recurring attacks of concomitant exotropia each followed by transient esotropia. *Arch. of Ophth.*, 1943, v. 30, Dec., pp. 727-731.

The patient, a Jewish female, first noticed disturbances of the ocular muscles seven years ago at the age of 28 years. Since that time she has had approximately 24 similar attacks. Typically the muscle disturbance has consisted of a severe nonparetic exotropia or exophoria, followed by a transient esotropia. The exophoric and the esophoric phase of an attack each has lasted about one week. At the onset of each attack the patient has had severe headache, nausea, and other symptoms. The entire disturbance is attributed to migraine. Hysteria and other disease factors have been excluded. The possible mechanism of the oculomotor disturbance is discussed in some detail. The phenomena seem best to be explained by the assumption that a vasomotor disturbance associated with migraine first depressed and then temporarily raised the tonus of Perlia's nucleus.

CONJUNCTIVA

Allen, T. D. Epidemic keratoconjunctivitis from a subjective viewpoint. *Amer. Jour. Ophth.*, 1944, v. 27, Jan., pp. 16-18; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41.

Paradoksov, L. F. Streptocide in the therapy of trachoma. *Viestnik Oft.*, 1943, v. 22, pt. 2, pp. 41-46.

A review of the literature and a report of the author's clinical investigations on 150 cases, five of which are reported in detail. The treatment consists in the internal administration of 0.3 gr. five times daily for ten days, and a repetition of the ten-day course of treatment two to five times, with a five-day interval between courses. Streptocide powder was used locally following expression. The conclusions are that streptocide is an effective agent in the therapy of trachoma; that it is possible to cure suitable cases of trachoma with this agent alone; that better results are obtained by combination of mechanotherapy, in the form of expression and massage, with interrupted courses of streptocide; that

streptocide rapidly reduces the acute inflammatory phenomena in the cornea and conjunctiva, and that streptocide powder used locally gives very encouraging results, being especially effective in pannus and corneal ulcers. (2 tables.) Ray K. Daily.

Pletnieva, H. A: Oculoglandular tularemia. *Viestnik Oft.*, 1943, v. 22, pt. 1, pp. 11-16.

Tularemia becomes an important infection in wartime. While its mortality is low, it rapidly assumes epidemic proportions, and, lasting for months, it causes prolonged periods of disability. The infection may come from hides of infected animals, or from bites and the blood of vermin, flies, mosquitoes, fleas, and mice. The infection may be carried by birds, cats, dogs, horses, or cattle. Infected water-supply and delayed milling of grain are factors in spreading the infection. The possibility of infection from one person to another is still a matter of dispute, but Mitzkevich is said to have produced oculoglandular tularemia in a patient by inoculation of secretion from a papule of a patient with the disease. The author proposes that, in view of our present knowledge of this infection, the term Parinaud's conjunctivitis shall be limited to oculoglandular tularemia, and shall not include cases caused by syphilis or tuberculosis.

Some ophthalmologists regard Parinaud's conjunctivitis as a clinical symptom-complex the etiology of which may vary. Pletnieva believes that with the present laboratory facilities Parinaud's conjunctivitis should be considered synonymous with tularemia. The two important diagnostic tests are the agglutination reaction and the skin test for tularemia. Four cases of oculoglandular tularemia are reported, in

two of which the erroneous diagnosis of dacryocystitis was made, because of the presence of a papule in the region of the lacrimal sac, with a necrotic center. The treatment is symptomatic. Convalescent serum is very effective and is indicated especially in the oculoglandular form to hasten resolution of the conjuncival process.

Ray K. Daily.

Shane, S. J. Oropharyngeal ulceration with conjunctivitis and skin lesions. *Canadian Med. Assoc. Jour.*, 1943, v. 49, Oct., pp. 309-311.

Four cases characterized by severe conjunctivitis, marked ulceromembranous stomatitis, obscure skin lesions, and generalized toxemia, with marked prostration, are described in detail. In the author's patient, the condition became much worse after sulfonamide therapy and was at first ascribed to that therapy. The eyelids were swollen and there was a thin seropurulent conjunctivitis from which the only smear apparently taken was one in which a gram-positive diplococcus was found. Smears from the mouth contained *Borrelia vincenti* and other organisms which were apparently incidental. The possibility of a primary virus infection seems not to have been considered.

Charles A. Bahn.

Williams, H. C. M. Cutaneous and conjunctival diphtheria. *Brit. Med. Jour.*, 1943, Oct. 2, pp. 416-417.

During the eight months prior to April, 1943, there were admitted to the Isolation Hospital, Southampton, from a military hospital, 19 patients who had lesions of the skin or eyes from which the diphtheria organism had been isolated. Of these, 12 were infected with virulent and 4 with avirulent organisms; in the remaining cases tests for

virulence were not carried out. Brief summaries of the 19 cases are given.

No toxemias could be ascribed to the action of diphtheria bacilli in any of these cases. No paralysis ensued. Membranes were seen in three cases of cutaneous infection and in one of conjunctival infection. In all the other cases the lesions had the usual characteristics of the skin condition as originally or subsequently diagnosed. The recognition of cutaneous diphtheria among patients with a variety of skin infections suggests the need for more frequent bacteriologic investigation in such cases. Charles A. Bahn.

6

CORNEA AND SCLERA

Allen, T. D. Epidemic keratoconjunctivitis from a subjective viewpoint. *Amer. Jour. Ophth.*, 1944, v. 27, Jan., pp. 16-18; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41.

Goldenberg, A. Z. The use of albucide in the therapy of seriginous and purulent corneal ulcers. *Viestnik Oft.*, 1943, v. 23, pt. 1, pp. 34-38.

This is a report of a clinical investigation on the use, in corneal lesions, of sodium acetyl sulfanilamide, a water-soluble sulfa preparation manufactured in the U.S.S.R. Of 90 patients treated, 66 had deep purulent corneal ulcers and nine had total corneal involvement. In 64 the ulcer was central, and in 17 peripheral. Eight cases had corneal perforation on admission, and seven a descemetocoele. Bacteriologic studies were made in 65 cases, and the pneumococcus was found in 86 percent. The method of treatment finally arrived at consists of blowing the powdered drug on to the cornea every three hours day and night for the first day, and only during waking hours after the first day.

The only other drug used in these cases was atropine or eserine, as indicated. The tabulated data show that in 60 patients the ulcer was clean and completely covered with epithelium in ten days; and in 39 of these in five days. In 14 cases the ulcer was covered with epithelium in 10 to 15 days. Healing was accompanied by formation of a firm flat cicatrix, restoration of the anterior chamber without the development of corneal staphyloma, absorption of corneal infiltrates, and early abundant vascularization around the ulcer. The advancing edges of seriginous ulcers were arrested on the second day, and hypopyon was absorbed in from 1 to 4 days in 18 of 24 patients. In 9 out of 71 cases vision was the same as on admission, and in 62 it was better than on admission. The average hospitalization time was 19 days but patients with total corneal involvement stayed in the hospital an average of 35 days. Iritis, marked hyperemia, rigidity of the iris, and a tendency to synechia delayed recovery in spite of the favorable process in the corneal lesion. It appears therefore that albucide does not influence the process in the iris as it does in the cornea. The author also notes that local application of this drug does not prevent penetration of the infecting agent into the deep ocular tissues. Ray K. Daily.

Kalfa, S. F. Ether in the treatment of corneal diseases. *Viestnik Oft.*, 1943, v. 22, pt. 2, pp. 23-25.

This is a tabulated report of 25 cases of keratitis (herpetic 6 cases, disciform 4, recurrent erosions 3, traumatic 6, ulcer 1, corneal erosion 1, ulcerative pannus 4) treated with repeated topical applications of ether, with satisfactory results. The only case where it was ineffective was one of seriginous ulcer.

The ether applications are analgesic, and not painful as are iodine applications. Kalfa reports briefly an intractable case of corneal herpes following a cataract extraction, which case responded promptly to ether applications.

Ray K. Daily.

Leopold, I. H. *Keratoconus posticus circumscriptus*. Arch. of Ophth., 1943, v. 30, Dec., pp. 732-734.

Two types of abnormal curvature of the posterior surface of the cornea have been described. One form is called keratoconus posticus and is characterized by a perfectly regular curvature, but with unusually short radius, for the entire posterior surface. The other form, called keratoconus posticus circumscriptus, consists of a localized area of increased curvature. In each type the anterior corneal curvature is perfectly regular and the abnormality is the result of thinning of the posterior corneal layers.

A case of this circumscribed lesion is reported in a Negress of 36 years. The left cornea showed an oval opacity below and nasal to the pupillary zone. Slitlamp examination disclosed that the cornea was only about one half the normal thickness in this area and that the thinning was confined to the posterior layers. The eye showed no other evidence of disease and no sign of trauma. The best vision obtained with correction was 6/30. The patient stated that the vision of this eye had always been poor, and no history of injury or disease could be elicited. The author summarizes the findings in three cases previously described by other observers. (Two illustrations, references.)

John C. Long.

Philpot, F. J., and Pirie, A. Riboflavin and riboflavin adenine dinucleo-

tide in ox ocular tissues. Biochem. Jour., 1943, v. 37, July, pp. 250-254.

To help explain the sensitiveness of the cornea to riboflavin deficiencies, ox eyes were examined separately by microbiological estimations and by the d-amino oxidase technique. The results were much alike. By either method the riboflavin content of the vitreous, lens, aqueous, and corneal stroma was found quite low, but that of the ocular conjunctiva and corneal epithelium was much higher, about 2 mg. per 100 gm. of total flavin. The higher content of the lacrimal glands, 6.5 mg. per 100 gm., and of the meibomian glands, 4 mg. per 100 gm., suggests that a part of the riboflavin content of the corneal epithelium comes from the tears and the meibomian secretion. This is of interest because in riboflavin deficiency advancement of limbal blood vessels on to the cornea may occur or may be hastened if the deficiency is not made up from the secretions of the lacrimal and meibomian glands.

UVEAL TRACT, SYMPATHETIC DISEASE AND AQUEOUS HUMOR

Duke-Elder, S., and Davson, H. The significance of the distribution ratios of nonelectrolytes between plasma and the intraocular fluid. Brit. Jour. Ophth., 1943, v. 27, Oct., pp. 431-434.

The authors take issue with the statement of Kinsey and Grant (Amer. Jour. Ophth., 1943, v. 26, July, p. 781) that at equilibrium the concentrations of the substance considered, electrolyte or nonelectrolyte, will not be equal in both fluids when there is a flow of aqueous humour away from the anterior chamber by some drainage channel, namely Schlemm's Canal. The fal-

lacy of this statment is proved mathematically by the second law of thermodynamics, which states that a system of this kind can only be maintained at a nonequilibrium position by the continued performance of work on it. Drainage of fluid away from the anterior chamber is not capable of performing the necessary work on the system, so that in the absence of secretory activity the concentration changes claimed are excluded by the law referred to. Louria, Milton. **Tuberculous adenitis with iridocyclitis.** Quarterly Bull. Sea View Hosp., 1942, v. 7, Oct., pp. 444-447.

A 14-year-old schoolboy had fever, swollen glands in the groin, swelling of the eyelids, disturbance of vision, and a rash on the legs. There were frequent drenching sweats, particularly at night, and the temperature ranged from 101 to 104 degrees. The ocular diagnosis was of bilateral iri-

docyclitis, and both this and the inguinal adenitis were attributed to tuberculosis of an acutely disseminated character. There were a number of adhesions of the iris to the anterior lens capsule, with many large spots on the posterior surface of the cornea. Excised inguinal nodes showed tuberculosis. After a positive skin reaction with a 1-to-10,000,000 dilution of tuberculin (bacillary emulsion); the patient was placed on tuberculin therapy. In ten weeks the body weight had increased from 128 to 163 pounds, and almost all the ocular and other symptoms had disappeared, with recovery of vision of 20/20 in each eye. The author feels uncertain how much credit should be given to the tuberculin therapy.

W. H. Crisp.

Lowenstein, O., and Givner, I. **Pupillary reflex to darkness.** Arch. of Ophth., 1943, v. 30, Nov., pp. 603-609.

In 1939 Lowenstein described a pupillary reflex which he called the "reflex to darkness." In order to elicit this reflex both eyes of the subject tested are adapted to a constant level of illumination in which darkness is a periodic stimulus. The resulting movements of the pupils are recorded by pupillography. The phenomenon consists of primary dilatation followed by the second phase of contraction and secondary redilatation.

The authors state that the reflex to darkness is frequently more susceptible to the influence of pathologic conditions than is the reflex to light. In a patient operated on for pinealoma, dissociation between the reflexes to light and to darkness was observed. The former were practically absent, and the latter were exaggerated. This dissociation of pupillary reflexes suggests the existence of separate pathways for the

reactions to light and to darkness. The authors believe that there must exist at least one point in the brain where the pathways of the reflexes to light and to darkness are not identical. (6 figures, references.)

R. W. Danielson.

Riddell, W. J. Iris color changes in middle life. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 183-187.

The author classified the color of the iris according to (1) the general color (blue, gray, green, yellow, tan, and chocolate), (2) the presence or absence of diffuse color, and (3) the presence or absence of spots or little masses of color. A series of 500 patients, 220 males and 280 females, were coded by this method. It was shown that the different classes were not homologous in respect to sex.

The changes in eye color seem to occur regularly during adult life, and to occur much earlier in women than in men. The changes tend generally to range from a class containing an excess of men to one containing an excess of women, and from the more masculine or juvenile classes to the more feminine or senile classes. GLAUCOMA AND OCULAR TENSION

Benedict, W. L. The surgical treatment of glaucoma. *Pennsylvania Med. Jour.*, 1942, v. 45, Aug., pp. 1167-1172.

The various surgical procedures in

general use are briefly reviewed, with some indication as to the type of case suitable for each operation.

W. H. Crisp.

Boyd, J. L. Quantitative comparison of methods of administering physostigmine. *Arch. of Ophth.*, 1943, v. 30, Oct., pp. 521-525.

Physostigmine was applied to the eyes of albino rabbits by several different methods and the concentration of the drug in the aqueous was then determined by bioassay on white mice. It was found that application of a 0.25-percent physostigmine-salicylate ointment gave a higher concentration in the aqueous humor than instillation of a 0.5-percent solution in distilled water. A lamella containing 0.11 mg. of physostigmine salicylate was twice as efficient as the ointment. A 0.5-percent physostigmine sulphate solution in a water-soluble jelly and a similar solution containing a wetting agent each produced a concentration in the aqueous approximating that produced by the lamella. The wetting agent, zephiran, is incompatible with salicylates, so physostigmine sulphate was used in these experiments. Iontophoresis employing a 2-ma. current for two minutes, with a 0.1-percent aqueous solution of physostigmine salicylate, increased the concentration $3\frac{1}{2}$ times that obtained by instillation of 0.5 percent physostigmine sulphate with a wetting agent. Four instillations of a 0.5-percent physostigmine-sulphate solution containing zephiran gave a concentration twice that obtained by four instillations of a 0.5-percent aqueous solution but less than half that obtained by iontophoresis with a 0.1-percent aqueous solution and a current of 2 ma. for two minutes. John C. Long.

Freiman, George. **Clinical study and review of tonometry.** Arch. of Ophth., 1943, v. 30, Oct., pp. 526-546.

This is a detailed discussion of the principles and instruments involved. Direct manometry is the only scientifically accurate method of measuring the true intraocular pressure. As this is clinically impractical, all methods of tonometry involve indirect calculations based on the incompressibility of the globe.

The Schiötz instrument is discussed in great detail, comparing this instrument with the McLean among others. Schiötz insisted that measurements be recorded in terms of the scale-reading with the particular weight used, rather than in millimeters of mercury. Recording in millimeters of mercury gives the impression of a degree of scientific accuracy that is not yet attainable. The McLean instrument is essentially a modification of the Schiötz type. It differs mainly in that (1) the scale is inverted so that it can be read close to the patient's eye, (2) the weight is constant, and (3) the instrument is read directly in millimeters of mercury. The author reports a series of 410 measurements with the Schiötz and McLean tonometers, giving a comparison of their readings. Adler, Berner, and Meyer had reported that the Schiötz, McLean, and Gradle instruments were sufficiently accurate for clinical purposes. The Bailliart and Souter tonometers differ from any of the above in that the pressure is applied to the eye by a spring rather than by gravity. Each of these instruments is found valuable by some workers.

Attention is called to the inaccuracy with which some of the tonometers are made. A wide variation has been found in the weight and construction of Schiötz instruments. In recognition of

the need for standards in construction, the American Academy of Ophthalmology and Otolaryngology has appointed a Committee on Standardization of Tonometers. (2 tables, references.)

John C. Long.

Garrow, A., and Lowenstein, A. **Calcification in a hydrophthalmic eye.** Trans. Ophth. Soc. United Kingdom, 1942, v. 62, pp. 189-197.

The author reports a case of monocular hydrophthalmos because of its possible relationship to the group of congenital anomalies known as phacomatoses (birth marks) and particularly to Sturge Weber's disease. In that disease hydrophthalmos is associated with nevus flammeus of parts supplied by the trigeminal nerve and convulsive symptoms indicative of changes in the cerebral blood vessels.

The patient was ten years old when the right eye was removed. She had been first seen at the age of 3½ years with a history of having had the large eye for one year. The tension varied between 40 and 60 mm. Schiötz until after a trephining during the first year of observation, when the tension became and remained subnormal. Three years later the eye became irritable, and it was so at intervals until still three years later it began to shrink and so was removed.

The cornea contained many blood vessels and blood was present in the substance of the cornea. Descemet's membrane was folded and one rupture found. The anterior chamber was densely packed with connective tissue, and a wavy piece of Descemet's membrane was found embedded in this connective tissue. The anterior capsule of the lens was folded and formed a wavy uninterrupted line. There was a broad layer of subcapsular organized exudate.

Degenerated lens substance was found to be freely sprinkled with lime. Fibrinous exudate was present in front of and behind the choroid, and the ciliary body and choroid were separated from the sclera. Fluid infiltration had divided the ciliary body into bundles. The choroidal separation from the sclera seemed to be associated with the fluid effusion, and there was also a large subretinal effusion.

Around the optic nerve there was an overgrowth of blood vessels resembling an angioma, and covered by a sheet of connective tissue. Another mass of vascular spaces was found at the anterior boundary of the retina. The calcification of vessels of the angioma was not uniform.

The retinal tissue and blood vessels were heavily impregnated with lime, and there were varying degrees of calcification of the retinal blood vessels. Some ganglion cells of the retina were also calcified. (8 illustrations.)

Swan, K. C. Carbaminoylcholine chloride in petrolatum. *Arch. of Ophth.*, 1943, v. 30, Nov., pp. 591-592.

Carbaminoylcholine chloride is a synthetic drug introduced in 1932 as a long-acting substitute for acetylcholine. Inasmuch as the drug produces miosis and cyclotonia and decreases intraocular pressure, it is used as an agent in the treatment of glaucoma.

The drug has a high affinity for water and a low affinity for lipids. Like other substances with these properties, it penetrates the normal human and rabbit cornea more readily when ad-

ministered as a suspension in a pure olive-oil or petrolatum base than when given in a simple aqueous solution or in one containing zephiran chloride or in ointment bases containing hydrous wool fat.

Clinical experiments were made on a group of 15 eyes (nine patients) with chronic noncongestive glaucoma. Pilocarpine administered three or four times daily was ineffective in controlling the tension or in preventing visual loss. Carbaminoylcholine chloride (1.5 percent in 0.03-percent solution of zephiran chloride) administered three to four times daily was effective in keeping the tension below 30 mm. Hg (Schiötz) and in preventing loss of visual field in 11 of the 15 eyes during periods of five months up to three years. However, carbaminoylcholine chloride (1.5 percent) in petrolatum administered only twice daily was equally effective in controlling the tension in these eleven eyes. In two eyes the tension was not consistently controlled by carbaminoylcholine chloride in solution of zephiran chloride when the drug was administered at home three to four times daily, whereas administration of the ointment twice daily at home was successful. CRYSTALLINE LENS

Falls, H. F., and Cotterman, C. W. Genetic studies of ectopia lentis. *Arch. of Ophth.*, 1943, v. 30, Nov., pp. 610-620.

The present report on the inheritance of ectopia lentis is based on the study of a single genealogical tree displaying this relatively rare ocular anomaly. The pedigree includes six generations, in which 157 individuals were examined.

Twenty-four with ectopia lentis were observed, five as judged by the history were probably affected, and two unaffected members were regarded as gene carriers.

The pedigree of ectopia lentis displays dominant inheritance of the anomaly. No conspicuous associated anomalies of the iris, cornea, or pupil were observed. Cataractous changes were common sequelae of the dislocation of the lenses. Chronic noninflammatory glaucoma and secondary glaucoma were frequently noted. Anthropometric measurements taken on all members of this pedigree failed to indicate any association between ectopia lentis and the length of the extremities, such as is found in the syndrome of arachnodactyly. To a considerable degree ectopia lentis adversely affects the physical and mental well-being, the educational achievement, and the economic status of the affected person.

The authors give a résumé of the surgical approach and emphasize that surgical intervention in the treatment of ectopia lentis is a serious and dangerous undertaking. The "treatment" is, of course, preferably prophylactic. (2 figures, references.)

RETINA AND VITREOUS

Ballantyne, A. J. **The ocular manifestations of spontaneous subarachnoid hemorrhage.** Brit. Jour. Ophth., 1943, v. 27, Sept., pp. 383-414. (See Section 12, Visual tracts and centers.)

Drews, L. C., and Minckler, J. **Mas- sive bilateral preretinal type of hemorrhage associated with subarachnoidal hemorrhage of brain.** Amer. Jour. Ophth., 1944, v. 27, Jan., pp. 1-15. (8 illustrations, references.)

Knapp, Arnold. **Peripheral retinal holes without detachment.** Arch. of Ophth., 1943, v. 30, Nov., pp. 585-590.

The author reviews the literature and reports five cases showing peripheral retinal holes without detachment. It is believed that the lack of detachment even in the presence of a hole is

due to formation of chorioretinal adhesions and to the fact that for some reason the usual factors in the production of detachment have not become operative. Knapp reviews the usual causes of detachment, such as gravity and adhesions, and liquefaction and movement of the vitreous. The non-development of a retinal detachment may be due to absence of any one of these factors.

As for treatment, the patient should, of course, be kept under observation. Some authors believe surgery is indicated, but Knapp does not favor it. At any rate, if surgery is attempted some very simple procedure should be used. (References, 1 figure.)

R. W. Danielson.

Lindsay-Rea, R. **Technique of retinal-detachment operations.** Trans. Ophth. Soc. United Kingdom, 1942, v. 62, pp. 277-284.

The author describes the method with which he has obtained good results in the operative care of retinal detachment. Retrobulbar injection is used and the cornea is kept clear for use of the ophthalmoscope during the operation. A fine needle with thread is passed through the sclera at a point corresponding to the meridian in which the tear is situated. This is used in turning the eyeball. The position of the tear is marked with India ink. In this region a bent catholysis-needle is inserted, and the fundus is then examined. If the needle is not at the tear it is to be reinserted. Upon localization a barrage of diathermy micropunctures is made around the area. Glass or ivory retractors should be used. A continuous fine catgut suture is used to close the conjunctiva. The eye is examined one week later. The retina is usually found replaced by two or three weeks later.

Pinhole spectacles are then put on and plenty of light admitted to the room. The patient is allowed up at the end of three or four weeks and the pinhole spectacles are used two weeks longer. (7 illustrations.) Beulah Cushman.

Lloyd, J. P. F. **Subhyaloid hemorrhage following "T. A. B." inoculation.** Brit. Jour. Ophth., 1943, v. 27, Oct., p. 461.

A case of extensive subhyaloid hemorrhage in front of the macula is reported following routine immunization with T.A.B. (typhoid-paratyphoid). Vision was reduced to hand movements. It had not improved a month later, although the retinal vessels could be seen through the vitreous haze. After an interval of two months, there was still considerable unabsorbed hemorrhage in the vitreous.

Edna M. Reynolds.

Mutch, J. R., and Mackay, D. **The detection and significance of melanophore expanding substance in urine and blood with special reference to retinitis pigmentosa.** Brit. Jour. Ophth., 1943, v. 27, Oct., pp. 434-449.

Vertebrates show two striking examples of pigment migration. One is migration of pigment within the skin melanophores of cold-blooded vertebrates. The other is migration of the retinal pigment in amphibia and fish in response to varying light intensity.

It is well established that the skin-melanophore response is mediated by a melanophore-dispersing hormone (B hormone) secreted by the intermediate lobe of the pituitary. Mammals, including man, have no skin melanophores like those in amphibia and fishes. Yet the pituitary glands in mammals are rich in B hormone or a substance with similar action. Extracts from the hypo-

thalamus, the eye, blood, aqueous humor, cerebrospinal fluid, urine, and colostrum also show the presence of B hormone.

The only cells in mammals which might be comparable to the skin melanophores of amphibia and fish are the retinal pigment cells of the eye. B hormone might therefore mediate changes in the pigmented layer of the retina. Experiments to date have not proved that B hormone plays any physiologic role in vision. There are no data to indicate the role of B hormone in pathologic conditions such as retinitis pigmentosa.

It was the recognition of retinitis pigmentosa as a feature of the Laurence-Moon-Biedl syndrome which first prompted the idea that the latter disease might be associated with diencephalic and endocrine disturbances. Dax, by his demonstration that urine samples from 20 retinitis pigmentosa patients when injected into frogs expanded the skin melanophores (*Amer. Jour. Ophth.*, 1938, v. 21, p. 1198, and 1939, v. 22, p. 572) led to renewed interest in the interpretation of retinitis pigmentosa as an endocrine or diencephalic disturbance.

The most widely accepted theory of the etiology of retinitis pigmentosa is that the degeneration of the neuroepithelium is primary and the vascular sclerosis secondary. Another theory is that it is due to an endocrine disturbance. The abnormal hormonal influences are believed to arise from a congenital lesion in the pituitary-hypothalamic system. The presence of a melanophore-expanding substance in the urine of retinitis-pigmentosa patients is considered particularly significant.

Experiments are reported in which blood samples from nine retinitis-pig-

mentosa patients were assayed and compared with blood samples from seven normal controls. Details are given of the process of extraction and assay employed. Only three of the nine retinitis-pigmentosa samples were definitely positive, and two of the seven control samples gave a positive result. It is concluded that the blood of retinitis-pigmentosa patients does not regularly contain a melanophore-expanding substance, and that such a substance may occasionally be present in normal bloods.

A further experiment is described to show that in the rabbit the B hormone, injected intravenously, disappears very rapidly from the circulation. (3 tables, references.) Edna M. Reynolds.

Post, L. T., and Sanders, T. E. Temporal arteritis. *Amer. Jour. Ophth.*, 1944, v. 27, Jan., pp. 19-25; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41. (3 illustrations, references.)

Steven, D. M. Experimental human vitamin-A deficiency. The relation between dark adaptation and blood vitamin-A. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 259-275.

The author has attempted by experiments to discover whether there is any correlation between poor dark-adaptation or night blindness and low values of blood vitamin-A. Previous experiments have presented evidence that for each individual there is a critical level of blood vitamin-A below which dark adaptation begins to show impairment, this being an individual characteristic which may differ greatly in different persons.

For the experimental work the author kept volunteers on a controlled diet deficient in the one factor he wished to investigate.

After pooling the findings in nine subjects he comes to the conclusion that all cases of night blindness which show blood vitamin-A values above 75 i.u. per 100 ml. of plasma are unlikely to be of nutritional origin. In six individuals a high degree of correlation was found between the rise of the visual threshold and the fall of the blood-vitamin-A level. (6 figures, 3 tables, references.)

OPTIC NERVE AND TOXIC AMBLYOPIAS

Adrogué, E., and Insausti, T. *Etiology of papilledema*. Arch. de Oft. de Buenos Aires, 1942, v. 17, May, p. 285.

The authors record in tabulated form 140 cases of papilledema studied during the last four years. Table no. 1 contains the findings, diagnosis, and localization in each case. Table no. 2 is a résumé of table no. 1. Table no. 3 presents the etiology of every case in this series. Table no. 4 records the intra-ventricular pressure. In three subtables are presented the clinical data concerning the cases of unilateral papilledema, those with bilateral papilledema more marked on one side, and those in which the papilledema was equal in both eyes. The article does not lend itself to abstracting.

Plinio Montalván.

Astakhova, A. P. *The action of anti-freeze on the eye*. Viestnik Oft., 1943, v. 22, pt. 2, pp. 33-35.

The author examined ophthalmoscopically thirty patients poisoned with anti-freeze. In six fatal cases directly due to heart and circulatory failure, the retina was cyanotic. In five fatal cases, because of secondary degeneration of the internal organs, the fundus veins

were dilated. There was one case of optic neuritis and one of pale discs. In 17 cases the fundus was normal. The conclusions are that anti-freeze is a neurovascular poison, with no predilection for the optic nerves.

Ray K. Daily.

Montgomery, E. C. *Intraocular neuritis*. Jour. Iowa State Med. Soc., 1943, v. 33, July, p. 298.

Two children, ten and twelve years old, had acute intraocular neuritis. In the older child after sulfadiazine therapy and tonsillectomy, the neuritis subsided within 11 months with 20/20 vision, but a peripheral visual-field contraction remained. In the younger child, under the same therapy, vision returned to 20/20 after two months. In view of the relationship of optic neuritis to disseminated sclerosis, the author believes that during the next few years these patients should be watched for neurologic symptoms.

T. M. Shapira.

Potter, W. B. *Visual impairment during tryparsamide therapy*. Arch. of Ophth., 1943, v. 30, Nov., pp. 669-687.

This review of the literature points out that, while tryparsamide is considered one of the best drugs in the treatment of neurosyphilis, unfortunately many cases of damage to the visual system have been reported after its use. Elucidation of the process, and of the character and frequency, of untoward visual effects from tryparsamide has remained incomplete.

The associated ocular problems lend themselves to general outline as follows: (1) as to the ocular effects of tryparsamide when syphilitic disease of the optic nerve preëxists; (2) as to the designation of lesions according to whether the damage to the retina or

optic nerve results primarily from syphilis, from the use of the tryparsamide, or from the fact that the tryparsamide was used during a period of involvement, inactive or active, of the optic nerve in a syphilitic process (Jarisch-Herxheimer reaction); (3) as to evaluation of the objective and subjective findings with regard to modification of tryparsamide therapy; (4), as to evaluation of factors related to individual dosage, number of injections, and subsequent series of injections; (5) as to the nature of the reaction to tryparsamide from the visual aspect; (6) as to the nature of the tryparsamide reaction from the pathologic aspect.

On all of these problems there is a difference of opinion among investigators and clinicians. Only a few of the statements and conclusions can be given. The drug is contraindicated except in the treatment of neurosyphilis, for which it is usually employed after six months of preliminary treatment with arsphenamine. The usual dose is 3 gm. intravenously. A minimum course consists of 12 weekly injections, although more prolonged use of the drug is ordinarily productive of better results. Primary atrophy of the optic nerve is the most frequent sort of neuropathy and is most frequently due to syphilis. Several authors have noted that there is no relationship, either qualitative or quantitative, between the appearance of the nerve head and the functional capacity of the nerve. Not all atrophy of the optic nerve occurring when the serologic reactions are positive is of the primary type; other changes in the oculonervous pathway may be at fault. Atrophy of the optic nerve cannot always be designated as primary or secondary on the basis of ophthalmoscopic examination alone. In optic-nerve atrophy, changes in the

fields usually occur previous to pallor of the optic disc.

There appears to be no evidence that sex, race, or age of patient is related to untoward visual effect during therapy with tryparsamide. A medicolegal case is reported where the patient won a suit on the ground that tryparsamide therapy was continued in spite of the plaintiff's complaint of increasing visual disturbances. Opinion seems equally divided between those physicians who when primary syphilitic optic-nerve atrophy is present would withhold the drug and those who under similar conditions would favor its use.

That the differential diagnosis between the normal appearance of the optic disc and that of primary syphilitic optic-nerve atrophy is not always clearly defined is attested by the fact that the color of the disc, the visual acuity, and the visual-field findings may yield contradictory evidence. But examination of the visual fields seems to offer the most effective information in regard to the exact basis of impairment of vision.

Suggestions to explain visual involvement include a hypothetic toxic effect of the drug on the nerve or retina, idiosyncrasy to the drug, factors superimposed by drug therapy on active syphilitic involvement (reactivation of a process) and the Jarisch-Herxheimer reaction. Problems such as the valence of the arsenic in the preparation, the structure of the tryparsamide molecule, and the factors of excretion and metabolism have been considered without establishment of conclusive opinions. (Bibliography.) R. W. Danielson.

Turner, J. W. A. Indirect injuries of the optic nerve. *Brain*, 1943, v. 66, June, pp. 140-151.

The author's study is based on 46 cases of indirect optic-nerve injury and excludes direct involvement by a projectile. These cases represent approximately 1.5 percent of 3,250 head-injury patients observed in two English head-injury centers. Included are falls, air-raid casualties, bicycle and motor-cycle accidents, accidents to pedestrians, car and lorry accidents, and miscellaneous.

In 35 cases, the impact was on the forehead or supraorbital region and on the same side as the visual loss; in six cases, the impact was in the region of the external angular process. In only one case was there a posterior head injury, and a contrecoup from an occipital injury was never observed to damage the optic nerve. The effect on vision was immediate and no delayed blindness was observed. Visual improvement, if it occurs, usually begins about the third day, rapidly progresses, and terminates about the fourth week. The prognosis of optic-nerve injuries is worse than that of injuries to other cranial nerves. The final corrected visual acuity in these 46 cases was: 6/60 or less, 23; 6/18 to 6/60, 21; better than 6/18, 14 cases. Visual fields included 8 cases with scotoma, pericentral, paracentral, and centrocecal, as the dominant feature. In 19 cases the defect was predominantly in the peripheral field, and in 19 cases the field changes were apparently mixed. In the severe cases disc pallor was usually first noted about the end of the third week, whereas in the less severe cases it occurred somewhat later. In severe injuries the pupils were equal, the pupil of the affected side showing a sluggish or no reaction directly, but giving a brisk consensual reaction. Pupillary inequality occurred only if third-nerve injury was coincidental. In only four cases was any abnormality found in the

optic canal by X ray. The author believes that the dominant pathologic lesion was a hemorrhage or thrombosis in the intracranial part of the optic nerve. Violent impingement against the bony wall of the canal ruptures small vessels in the septa of the nerve, with secondary local thrombosis and softening. Charles A. Bahn.

12

VISUAL TRACTS AND CENTERS

Balado, Manuel. *Retinal areas and cortical sectors*. Arch. de Oft. de Buenos Aires, 1942, v. 17, May, p. 250.

The author discusses the difference between the campimetric findings in lesions of the occipital cortical area and those involving the nerve-fiber bundles at their entrance to the globe, such as seen in glaucoma, toxic amblyopia, and juxtapapillary chorioretinitis. In the latter group of diseases the scotomata do not follow the vertical and oblique meridians of the visual field; whereas in the field defects produced by lesions situated in the cortical area the vertical meridian passing through the center of the fovea always divides the visual field into two halves, a blind half and a seeing half. The anatomical basis is explained. (Illustrations.)

Plinio Montalván.

Ballantyne, A. J. *The ocular manifestations of spontaneous subarachnoid hemorrhage*. Brit. Jour. Ophth., 1943, v. 27, Sept., pp. 383-414.

Five cases of nontraumatic subarachnoid hemorrhage are reviewed and the pathological findings are given in detail because of their bearing on the nature and origin of the ocular complications. Hemorrhages varied in distribution in each case but were widely distributed between the sheaths of the optic nerve,

in the orbit among the fat and muscles, surrounding the posterior ciliary nerves, ciliary ganglion, ophthalmic and posterior ciliary arteries, and around the vessels of the chiasm and optic tracts, as well as beneath the retina in all its layers, in front of the retina, and in the vitreous. Serial sections showed that the hemorrhages were not in continuity but were discrete and independent.

The author reviews the various theories which have been advanced as to the source of the blood found within the sheaths of the optic nerve and in the retina. Because he finds hemorrhages occurring simultaneously in so many other areas beside the optic nerve, the retina, and the vitreous, it is his opinion that such multiple hemorrhages can only be explained by a sudden rise of intracranial pressure causing stasis in all the venous channels which drain the tissues of the eye and the contents of the orbit. He suggests also that some of the clinical signs of subarachnoid hemorrhage, such as oculomotor paresis and disturbance of the conjugate movements of the eyes, may be explained by the occurrence in the mid-brain of hemorrhages similar to those found in the chiasm and optic tracts in one of the cases reported here. Clark, W. E. L. *The anatomy of cortical vision.* (Doyle Memorial Lecture.) *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 229-245. (See Section 19, *Anatomy, embryology, and comparative ophthalmology.*)

Fetter, W. J. *Subarachnoid hemorrhage.* *Pennsylvania Med. Jour.*, 1943, v. 46, June, p. 949.

The author reviews a series of 68

cases of subarachnoid hemorrhage hospitalized during a five-year period. He states that this disturbance occurs most frequently in cases of trauma, intracranial aneurysm, and arteriosclerosis. The abrupt onset of symptoms, signs of meningeal irritation, and the finding of an evenly blood-stained spinal fluid are characteristic. Prognosis is less favorable in hypertensives. As a rule, conservative treatment is the most satisfactory. T. M. Shapira.

Orton, S. T. *Visual functions in strephosymbolia.* *Arch. of Ophth.*, 1943, v. 30, Dec., pp. 707-711.

Children who make little progress in learning to read are quite naturally referred to the ophthalmologist. Many, however, if not the majority of these children have adequate vision and in reality present neurologic problems. Three distinct levels of elaboration may be recognized in cases of absence of visual functions normally acquired in early life. Disturbances at these levels are recognized respectively as cortical blindness, mind blindness, and word blindness. It is thought that only at the third level does the principle of bilateral dominance apply, and there is reason to believe that at this level the records in the two hemispheres are opposite in sign, and that one record must be omitted to prevent confusion.

In studying children with reading defects the author was struck by the inability of children to differentiate "b" from "d" and "p" from "q," and by their tendency to read many words from right to left instead of in the usual direction. Some of these children showed an unexpected facility in reading mirrored print and some also were skilled in mirror writing. The author suggests that these deviations are due to failure to acquire the normal adult

pattern of complete dominance by one hemisphere of the brain. The author further offers the term "strephosymbolia," or "twisting of symbols," as being less misleading than the older term, "congenital word blindness."

The relationship between eyedness and handedness is discussed in connection with reading defects. From the data collected the author concludes that children showing the strephosymbolia syndrome represent intergrades between right-sided and left-sided familial tendencies and that the reading disability follows fairly definite hereditary trends. It is interesting to note that such reading difficulties occur much more frequently in boys than in girls. (2 figures.) John C. Long.

Scheneley, W. G., Jr. Clinical approach to vertigo. *Dis. Eye, Ear, Nose, and Throat*, 1942, v. 2, July, pp. 198-201.

In question-and-answer form the author explains and illustrates the relationships which exist between vertigo and the organs of orientation, namely, the eyes, the semicircular canals, the ventriculus, the utricles of the middle ear, and the joints, muscles, and viscera. Vertigo following paralysis of the extraocular muscles does not last so long as that caused by paresis of these muscles. Aural vertigo is always associated with rhythmic nystagmus, the direction of which depends on the direction of the semicircular canal involved. The anatomic relationships and pathology of rhythmic nystagmus are explained at some length, as are galvanic rotational and caloric tests. Undulatory nystagmus caused by visual defects, either congenital or acquired early, especially of the central visual mechanism, is seldom associated with vertigo.

EYEBALL AND ORBIT

Inciardi, J. A. Unilateral exophthalmos. *Dis. Eye, Ear, Nose, and Throat*, 1942, v. 2, Dec., p. 359.

The more important causes of unilateral exophthalmos are classified. Each type is described, in order that the ophthalmologist may be aided in finding the etiologic factor concerned. The author gives detail of diagnosis and treatment in many types of this condition.

F. M. Crage.

Sverdlov, D. G. Spectacles with shields for hiding defects in and about the orbit. *Viestnik Oft.*, 1943, v. 22, pt. 2, p. 47.

The author urges the use of an opaque lens and a shield, instead of a bandage, to cover loss of tissue in and about the orbit. The shield may be made of any plastic material, and colored to match the spectacle frame. The advantages claimed for this device are elimination of irritation, especially in warm weather, accessibility of air to the skin and wound, and a more agreeable cosmetic impression. (One illustration.)

EYELIDS AND LACRIMAL APPARATUS

Dodds, G. E. A case showing partial deficient fusion of a maxillary process with lateral nasal process on one side. *Brit. Jour. Ophth.*, 1943, v. 27, Sept., pp. 414-415.

The patient had distortion of the right nostril with a hiatus showing the interior of the nose. This was merely

a cleft in the cartilaginous part of the nose, and the bony structure appeared normal. There was notching of both upper eyelids at the junction of the inner third with the outer two thirds of the lid. On the inner side of the left medial canthus, there was a blind shallow pit in the skin of the nose. Conduction of tears appeared normal and the eyes were normal. (One illustration.)

Edna M. Reynolds.

Hague, E. B. **Recent advances in eyelid surgery.** *Dis. Eye, Ear, Nose, and Throat*, 1942, v. 2, Dec., p. 353.

The article outlines the basic principles of surgery in the region of the eye and describes some relatively new procedures used in correcting ptosis, spastic entropion, and blepharopoesis. In late plastic lid-repair the author joins Dunnington and Wendell Hughes in decrying the use of the pedicle grafts because they create new deformities. Instead free grafts are recommended. Special emphasis is laid on type of sutures and their removal, and the technique of dressings. F. M. Crage.

Lewis, S. J. **Aneurysm in eyelid.** *Jour. Med. Assoc. Georgia*, 1943, v. 32, June, p. 185.

A luetic 19-year-old colored female had an aneurysm of the upper eyelid, diagnosed clinically by a palpable thrill synchronous with the pulse. At operation under general anesthesia the palpebral branch of the ophthalmic artery showed an aneurysm, which was ligated. Severe proptosis and chemosis followed, but at operation subsided.

T. M. Shapira.

Paula Santos, B. **Phenomenon of Marcus Gunn.** *Arquivos Brasileiros de Oft.*, 1943, v. 6, June, pp. 68-98.

As a preliminary, the author calls

attention to the distinction between the phenomenon of Marcus Gunn (the jaw-winking phenomenon) and the Marcus Gunn sign (pressure by a retinal artery upon the vein at a crossing). The greater part of this 31-page article is occupied with a restatement of what the author describes as the most complete work on the Marcus Gunn phenomenon, the paper by H. Villard which appeared in the *Bulletin of the French Society of Ophthalmology*, 1935, pages 725-755.

From a survey which Paula Santos suspects of being not altogether complete, he estimates that the world literature of the subject records more than 149 cases. A four-page bibliography is appended.

The single new case now recorded is that of a seven-year-old Brazilian boy. His parents had no trace of consanguinity. There had been six children, five of which survived, and none of which showed organic anomalies. No case of palpebral ptosis was recorded in the ascendants. The behavior of the affected eye is shown by four excellent photographs, with various positions of the lower jaw.

The right eye had normal visual acuity, the left only $\frac{1}{8}$. The affected eye had a hyperopia of 2 D., correction of which did not improve vision. There was paralysis of the left superior rectus muscle, so that the eye had limited upward motion.

Lowering of the mandible was accompanied by elevation of the left upper lid, the elevation being proportionate to the amount of opening of the mouth. A similar effect upon the eyelid was produced by lateral movements of the jaw, the elevation being more marked when the jaw was drawn to the opposite side. Lid elevation also occurred during loud speaking or

shouting. It was not elicited by whistling, swallowing, or backward inclination of the head. The ptosis could not be corrected voluntarily, but contraction of the frontal muscle induced an increase in the palpebral fissure.

The etiology of the anomaly is entirely unknown. The author considers various speculative theories. It has been suggested that the nucleus of the lid elevator and the upper end of the masticating nucleus might be anatomically united; but this idea is embryologically untenable, because the two nuclei have distinctly different locations in the brain. Terrien has pointed out that patients affected by congenital ptosis show a slight degree of the Gunn phenomenon, usually overlooked.

TUMORS

Carter, L. F. Dermoid tumor of the sclera. *Amer. Jour. Ophth.*, 1944, v. 27, Jan., pp. 67-70. (3 illustrations, references.)

Foster, J. Discission of traumatic hyaloid diaphragm. *Brit. Jour. Ophth.*, 1943, v. 27, Oct., pp. 462-464.

A case is reported in which a dense fibrous membrane in the vitreous was divided with a Ziegler knife introduced behind the ciliary body from the temporal side. No diathermy of the Ziegler puncture was performed. At the first dressing an advanced posterior cortical cataract was evident. It progressed to maturity in less than a week. Two lens discissions were performed, and with correction (+13.5 D. sph.) vision of 6/5 was obtained. (3 diagrams.)

MacCallan, A. F. Tumor of conjunctiva simulating tubercle due to trachoma. *Trans. Ophth. Soc. United*

Kingdom, 1942, v. 62, pp. 79-82. (See Section 5, Conjunctiva.)

Neame, Humphrey. Two cases of malignant melanoma of the iris. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 103-111.

Two cases of melanotic tumor of the iris were seen almost three years after operation. One had been treated with unscreened radium after incomplete removal by iridectomy. The other had been merely removed by iridectomy. An iridectomy is indicated when the neoplasm is small, well defined, and situated near the pupillary border, with normal intraocular tension and good vision. (9 illustrations.)

Beulah Cushman.

Picena, J. P., and Páez Allende, F. Concerning an achromatic melanoma of the choroid. *Arch. de Oft. de Buenos Aires*, 1942, v. 17, May, p. 255. (See also *Amer. Jour. Ophth.*, 1943, v. 26, p. 657.)

A woman eighty years old presented a retinal detachment in a blind eye. An acute attack of glaucoma developed and the eye was enucleated. Histopathologic examination disclosed a malignant melanoma of the choroid of the so-called achromatic or nonpigmented type, and special staining methods revealed the presence of granules of melanin. From morphologic studies of the tumor cells the authors agree with Masson that melanocytes are derived from the cells of the nerve sheath of Schwann and that choroidal melanomata are, consequently, neuroectodermal in origin. (Photomicrographs, bibliography.) Plinio Montalván.

Reuling, F. H. Glioma of the optic nerve. *Jour. Iowa State Med. Soc.*, 1943, v. 33, Sept., pp. 422-424.

Glioma of the optic nerve is quite rare, there being about one such case for every two hundred choroidal melanomas. It occurs in the first decade, with gradual loss of vision, and exophthalmos. Pain is not marked. Histologically, the tumors are classified as finely reticulated, coarsely reticulated, or coarsely fibrillated types. The case of a ten-year-old boy is presented, with history of painless exophthalmos of the left eye for two years. There was no light perception, and the optic-nerve head showed marked atrophy. The eyeball and tumor were removed. The Army Medical Museum diagnosed the tumor as "glioma of the optic nerve, chiefly coarsely fibrillated type." Gross and microscopic photographs and descriptions of the tumor are included in the paper.

INJURIES

Azarova, H. C. A report of two cases in which glass particles remained in the eye for long periods. *Viestnik Oft.*, 1943, v. 22, pt. 1, pp. 38-40.

During air raids the destruction of dwellings, and especially of windows, causes many ocular injuries with penetration of wood or glass splinters into the eyeball. Wood particles usually lead rapidly to suppuration. Metal particles are localized by X ray and are removed, the final outcome depending on the site and gravity of the injury, the type of metal, the skill of the surgeon, and the resistance of the patient. Glass is difficult to localize with the X ray, and it may remain in the eyeball for a long time without producing inflammatory phenomena: it is therefore often left alone in the eye if it appears to be tolerated. Nevertheless, the eye-

ball tends to free itself of the foreign body, which is sometimes extruded spontaneously after remaining in the eyeball for a long time.

Two cases are reported. A particle of glass lodged in the pars planum of the ciliary body in the left eye of a civilian, during a bombing raid. He developed a severe iridocyclitis, and was under treatment for ten weeks, during which time an unsuccessful attempt was made to extract the foreign body. After the operation the inflammation subsided, although for several months there were recurrent attacks of mild irritation, one of which was complicated by papillitis. The eye finally became quiet, and remained so for the year during which the case was under observation. There was a retinal detachment below and particles of glass could be seen in the vitreous. The second case was in a housewife whose right eye was injured during a bombing raid. She was found to have retinal detachment, and X-ray revealed a small intraocular foreign body and a large piece of glass in the antrum. The eye remained quiet, although blind, for 15 months, at the end of which time a particle of glass was spontaneously extruded from the original wound. Within the next three days the eyeball was lost from panophthalmitis, in spite of the vigorous use of sulfanilamides. Ray K. Daily.

Berens, C., Gara, P. F. de, and Loutfallah, M. Effect of sulfonamide ointment on healing of experimental wounds of rabbit cornea. *Arch. of Ophth.*, 1943, v. 30, Nov., pp. 631-644.

Because of the apparently growing importance of the sulfonamides in the treatment of civilian and military war wounds, it seemed desirable to study the effect of local treatment with an ointment containing 5-percent of sul-

fonamide compounds on the healing of experimental wounds of the cornea of rabbits. The wounds were produced (a) with sterile instruments (Graefe knives, wide keratomes, Hippel trephines) and (b) with similar instruments previously infected with hemolytic staphylococci.

Experimental wounds were produced on 88 corneas. Local use of the ointment referred to did not accelerate the healing of superficial or deep incised or trephined wounds of the cornea of rabbits if sterile instruments had been used to produce the injury. The ointment was of value in the treatment of wounds produced with instruments infected with *Staphylococcus aureus hemolyticus*. The results indicate therefore that local use of the sulfonamide compounds can be limited to cases in which chances of infection prevail. (References, two tables and twelve photomicrographs.)

R. W. Danielson.

Black, G. W. Results of treatment of traumatic cataract. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 215-222.

The author was able to make a follow-up examination on 40 patients out of 100 who during the previous ten years had had treatment for traumatic cataract. Of the 40 cases 34 showed perforating corneal injuries, and in 15 of these an intraocular foreign body was found. Divergent deviation was present in the majority of the patients, usually appearing a few months after the accident. It did not tend to occur when the cataract was partial and stationary.

In 22 cases the vision was no better than counting fingers, there being no possibility of improvement without further operation, and the poor vision

being due mainly to dense lens remnants and blocking of the pupil. Traumatic cataract with dislocation occurred twice in children, with loss of vision in one due to secondary glaucoma, and in the other associated with retinal separation. The author emphasizes that maximum mydriasis must be maintained after any injury to the lens or until healing and absorption have taken place. Beulah Cushman.

Davis, W. T. *Military ophthalmology*. *Amer. Jour. Ophth.*, 1944, v. 27, Jan., pp. 26-44. (References.)

D'Eramo, Cayetano. *Traumatic myopia*. *Anales Argentinos de Oft.*, 1942, v. 3, Oct.-Nov.-Dec., p. 207.

In a 25-year-old man a blow on the left eye with a fist resulted in a wound of the lower eyelid and reduced vision. The retinoscope showed 8 D. of myopia and vision was 6/6 with a -8 sphere. The myopia gradually diminished and at the end of 41 days the refraction was emmetropic and vision normal.

Eugene M. Blake.

English, P. B. Sap dermatitis and conjunctivitis caused by the wild fig (*Ficus Tumila*). *Med. Jour. Australia*, 1943, v. 1, June 26, p. 578.

Several cases are reported in soldiers. They were suffering from blistering of the skin of the forehead, the cubital fossae, and the genitals, as well as intense conjunctivitis and severe irritation of the nasopharynx. These men had been working in an area which contained two wild fig-trees. It is evident that the sap of the fig tree caused these lesions. Four cases of affliction of the eye are described in detail. Of these, two showed defect in the corneal epithelium. Only one was permanently impaired. In all the other

cases the lesions healed within a few days without permanent impairment of vision. Gertrude S. Hausmann.

Harkness, G. F. **Industrial ophthalmology.** *Industrial Med.*, 1943, v. 12, Oct., pp. 658-662. (See Section 18, Hygiene, sociology, education, and history.)

Kaminskaya, Z. A. **Clinical symptoms and therapy of indirect ocular injuries.** *Viestnik Oft.*, 1943, v. 22, pt. 2, p. 7.

This is a study of the pathology of the posterior ocular segment in ocular contusions, based on material seen in a base hospital. Ocular contusions were found most frequently in injuries of the lower outer orbital margin and the zygomatic arch. They occurred less frequently in injuries of the superior outer orbital margin, and were quite infrequent in injuries of the inner orbital wall and the nose. The history is fairly characteristic. Total loss or marked reduction of vision occurs immediately after the injury; frequently the patient sees a red fog. The symptoms may occur immediately, or they may be delayed for several days or months. Usually in cases of total loss of vision there was hemophthalmos, and in cases complaining of red vision there were vitreous hemorrhages. Hemorrhage into the vitreous associated with tears of the posterior hyaloid membrane is seen in the form of floating red bands. Reaching the anterior hyaloid membrane the blood becomes applied to its surface, or it permeates into the retrolental space, where it appears as a red band behind the lens. In some cases the vitreous becomes detached, and the hemorrhage is preretinal. In extensive detachments blood fills the folds in the hyaloid

membrane, and one sees reddish bands, swinging with movements of the eyeball, but not floating as do hemorrhages within the vitreous. In addition to vitreous hemorrhage, retinal hemorrhages of various intensity may occur. There appears to be no clear relation between the site of the retinal hemorrhage and that of the injury, although hemorrhages are observed more frequently on the side of the injury. Peripapillary hemorrhages are most frequent; they have a striated appearance, pointing to their location within the nerve layers of the retina. Second in frequency are macular hemorrhages. These may be continuous with the peripapillary hemorrhages, when they are also striated; or they may be limited to the macula and round in form, indicating localization in the peripheral retinal layers. Edema of the disc and retina may be encountered among the immediate symptoms. Choroidal ruptures in military injuries have an appearance entirely different from those seen in civil injuries. They may be found in any portion of the fundus and have the appearance of broken zig-zag intertwining lines. One gets the impression that the eyeball has suffered a severe insult as a result of which, so to speak, the choroid fell to pieces. Macular holes have occurred. The author saw several traumatic retinal detachments, but never a separation from the ora serrata. Optic neuritis was rare and recovered without leaving any sequelae. A few cases were without objective signs to account for the visual loss; most of these recovered vision although not always entirely. In these cases there was probably an edema of the external retinal layers, which when involving the macula caused immediately an intense impairment of vision. Partial permanent

visual loss is due to subsequent macular degeneration.

The late results of hemophthalmus are dense vitreous opacities, which reduce vision and may lead to retinal detachment. In several cases the author found synchysis scintillans. After absorption of the retinal hemorrhages, she found in several cases yellowish foci grouped in the periphery around the terminal vessels, and similar to those seen in the macula in hypertensive retinopathy. Usually edema of the retina subsided and vision was restored, although in one case there was a macular hole. Atrophic foci in the choroid are frequent. Hypotony, immediate or late, without iridocyclitis was seen in several cases.

The pathogenesis of these injuries Kaminskaya sees as a concussion within the eyeball, which in the anterior ocular segment causes subluxation of the lens, and in the posterior segment sets up a reverse wave which separates the vitreous from the membrana limitans interna. The vacuum left between the vitreous and the retina is conducive to hemorrhage, but the important factor is the change in the vessel wall itself. The primary spasm increases the permeability of the vessel wall, and the secondary dilatation facilitates the escape of blood into the tissues. The changes in the vascular wall are caused by the traumatic disturbance in ocular innervation. The hypotony usually present in a contusion of the eyeball indicates that an innervational disturbance in the secretory metabolism of the eyeball has taken place.

The immediate therapy should consist in inhalations of amyl nitrite to relieve the angiospasm. Later comes administration of calcium (1) by ionization, (2) internally, and (3) intra-

muscularly to diminish permeability of the vessel wall. Vitamin C serves the same purpose. To prevent subsequent development of retinitis proliferans, Zur Nedden's operation may be performed in extensive vitreous hemorrhages. For the absorption of vitreous opacities, iodine is given by ionization and internally. Blood transfusion was effective in one out of two cases. For the hypotony there is as yet no effective treatment. Ray K. Daily.

Kaminskii, D. C. Hole in the macula as a result of ocular contusion by firearms. *Viestnik Oft.*, 1942, v. 22, pt. 2, pp. 25-31.

Seven cases observed in an evacuation hospital are reported. Six were injured with a fragment of a mine, and one with a bullet. In six cases the ocular trauma was indirect, being associated with contusions and damage to the outer orbital wall. One case showed direct injury to the eyeball. In two cases the pathology developed six weeks after the injury and was limited to the macula, with the exception of chorioretinal foci at the periphery, which probably resulted from hemorrhages. The author believes that the pathology in the retina caused by contusion is similar to the process taking place in the brain; an edema of colloids, as a result of cellular shifts, and a disturbance in metabolism due to innervational disturbances in the vessel walls. Depending on its intensity, the edema may subside with functional recovery, or the macula may degenerate leaving a hole.

In three cases, immediately after the contusion there were vitreous opacities and retinal hemorrhages. After absorption of these the defect in the macula became apparent. The retinal hemorrhages, and also probably hemorrhages

into the suprachoroidal space, aggravated the destructive process in the injured macula. In one case of direct contusion the fragment entered the right orbit temporally and lodged in the superior orbital fissure. The foreign body thus traversed the entire depth of the orbit, passing between the outer orbital wall and the eyeball. No choroidal or retinal tear could be found, but the contusion led to pathologic changes in the macular colloids with subsequent macular degeneration. These six cases, differing in the type of injury and the extent of damage, have the same final visual result, a central scotoma. For therapy the author suggests antiedematous agents, locally and intravenously. (7 illustrations.) Ray K. Daily.

Karandasheva, K. M. A case of ocular contusion by a bullet. *Viestnik Oft.*, 1943, v. 22, pt. 2, pp. 48-50.

Entering at the outer side of the eyeball a bullet lodged in the posterior portion of the orbit. There was exophthalmos, with limitation of motion, choroidal and vitreous hemorrhages, and central retinal edema. Vision was 1/1000. The bullet was extracted a week after the injury, and at discharge the patient's vision was 2/100. The unusual feature of this case is the entrance of the bullet into the orbit without splintering the bone or shattering the eyeball. (3 illustrations.)

Ray K. Daily.

Kaznelson, A. B. Gunshot lesions of the orbit. *Viestnik Oft.*, 1943, v. 22, pt. 2, pp. 13-23.

In the present war, injuries caused by mine splinters are more numerous than bullet wounds. Of orbital wounds in an evacuation hospital, 23 percent were produced by bullets and 77 percent by mine fragments. The wide use

of mines and grenades results in numerous cases of multiple wounds of the face and eyes caused by flying splinters. The type and character of the damage depend on the caliber and size of the bullet, the shape of the splinters, their velocity, and the distance they travel. Because of the low resistance of the thin bony walls of the upper jaw, a shot from a distance of 800 to 1000 meters produces a through-and-through ragged wound. From a distance of 300 to 500 meters it causes numerous fractures with heavy destruction of the soft tissues at its exit. Striking from within a distance of 200 meters it produces a splintering injury. Because of ragged edges and rotating movements, splinter damage is more severe and extensive than that produced by bullets. Orbital injuries are rarely isolated and are usually a part of extensive damage to the face and skull. In 50 percent of the cases the paranasal sinuses were damaged, and in 24 percent the brain was involved. The appearance and size of the point of entry is not always indicative of the depth and extent of the damage. In 25 percent of the cases the fragments were found on the side opposite their entry, and in some cases the point of entry was at a distance from the orbit. There were cases in which the fragment entered through the lower lid of one eye, passed through the nose, and was arrested in the orbit of the opposite side. As a result, in the apparently severely damaged orbit the eyeball had symptoms of contusion, and in the good orbit the eyeball was perforated. Very frequently there is a disparity between the points of entry and the number of fragments shown by X ray, because the original fragment splinters on striking the bone and its fragments scatter in various directions. For this reason all orbital injuries

should be subjected to thorough clinical and roentgenologic study. The peculiarities of military injuries force the ophthalmologist to go beyond the orbital walls in order not to overlook injuries to the skull.

The clinical picture of these injuries varies greatly. The author proposes a classification based on the direction and extent of the wound and the relation of the foreign body to the orbit. The first division is into direct and indirect injuries. The direct are divided into diagonal, perpendicular, and contusion injuries. The diagonal and perpendicular are subdivided into those in which the bullet or fragment passes through the orbit, and those in which the destructive agent is arrested in the orbit. The clinical pictures for each of these types are described in detail.

The abundant blood supply of the face favors rapid healing of wounds, and accounts for the rarity of severe infections. Quite contrary to the rules for dealing with wounds in other parts of the body, all conjunctiva and lid tissue should be conserved, even if it appears hopelessly destroyed. One should leave in the wound all fragments of bone if they are attached to the soft tissue: osteomyelitis of the orbital bones in gunshot injuries is very rare, and fragments of bone serve to stimulate the reconstruction of fractured bones. The danger of gas infection on the face is negligible, and primary sutures should be introduced in order to prevent deformity of the lids, requiring subsequent plastic procedures. Particular attention should be paid to restoration of the conjunctival sac, because torn conjunctiva tends to adhere to bony fragments and to retract into the cicatrix. Wounds sutured even 8 to 12 days after the injury have healed well. Removal of accessible foreign

bodies should be attempted if they cause inflammatory phenomena, or, if they are located within the nasal sinuses. The military ophthalmologist should be conversant with injuries about the orbit and should know when to call in a surgeon or a neurosurgeon. Streptocide, a soluble sulfa drug, is used freely in the wounds. In exophthalmos due to retrobulbar hemorrhage it is well to suture the lids in order to safeguard the cornea. There is no indication for hasty enucleation of a destroyed eyeball. In cases in which a purulent discharge persists for a long time after enucleation one should suspect a fistula connecting the orbit with a nasal sinus which contains a foreign body. Roentgenographic investigation and elimination of the offending agent will usually be followed by cessation of the discharge. Ray K. Daily.

Liorber, G. C. **Retinal injuries.** *Viestnik Oft.*, 1943, v. 22, pt. 2, pp. 31-33.

A review of the literature on the etiology of retinal detachment, with special emphasis on macular holes, and including eight cases of holes in the macula reported in the Russian literature from 1910 to 1936. The author's own case was in a student, 14 years old, whose left eye was injured in an explosion of matches which he was grinding in a mortar. In addition to a contusion of the lids and a subconjunctival hemorrhage, he had a hole in the macula, which left him with a permanent central scotoma, and 0.2 visual acuity. Ray K. Daily.

Lippincott, S. W., and Blum, H. F. **Neoplasms and other lesions of the eye induced by ultraviolet radiation in strain-A mice.** *Jour. Nat. Cancer Inst.*, 1943, v. 3, June, p. 545.

Neoplasms and other lesions of the

eye induced by ultraviolet radiation are described. Pathologic changes are superficial, being confined primarily to the cornea. There may be inflammatory changes, and the iris and lens may be involved secondarily. The tumors observed have been sarcomas and hemangioendotheliomas of the substantia propria. Changes in the epithelium of the cornea suggest that carcinomas may occur at times. The possible etiologic rôle of sunlight in producing lesions of the human eye is discussed. (6 illustrations.)

Gertrude S. Hausmann.

McLane, J. N. Retinal hemorrhage in a case of rattlesnake bite. *Jour. Florida Med. Assoc.*, 1943, v. 30, July, p. 22.

A patient complained that, following the bite of a rattlesnake, the vision had been impaired in his eye. Examination of the fundus revealed a large round-shaped hemorrhage close to the macula area. Retinal hemorrhages are rarely recorded in patients bitten by poisonous snakes, chiefly because cases of very serious poisoning with involvement of the nerve center are seldom examined ophthalmoscopically before death.

Gertrude S. Hausmann.

McNabb, H. H. The treatment of traumatic cataract. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 207-213.

The author advises expectant treatment of traumatic cataract. In adult patients with a hard nucleus the progress must be watched very carefully, as many individuals are sensitive to the action of their own lens protein, and iritis, cyclitis, or endophthalmitis may develop. Wounds associated with penetrating injuries by splinters of wood, forks, and the like almost invariably become septic, and for them the use of

the sulfa drugs locally has been of great help.

Beulah Cushman.

Mann, I., and Pullinger, B. D. A study of mustard-gas lesions of the eyes of rabbits and men. *Amer. Jour. Ophth.*, 1943, v. 26, Dec., pp. 1253-1277. (25 illustrations, 2 tables.)

Markelova, Z. H. Nonperforating wounds of the eyeball and lids. *Viestnik Oft.*, 1943, v. 22, pt. 1, p. 27.

Of the ocular military injuries, 58 percent were nonperforating. Accurate diagnosis and prompt treatment in the field hospital permitted 38 percent of these to return to service; 62 percent were sent to a base hospital. The lids and cornea were injured most frequently; rarely the sclera and conjunctiva. Most severe are the corneal injuries, which if not cared for properly are rapidly complicated by iritis and synechia, with visual impairment. Early atropinization of such cases is important. All corneal injuries should be hospitalized until complete recovery. Premature discharge has frequently led to an aggravation of the inflammatory process. The sharp injuries and blows as a rule injured the lids; blunt injuries affected the cornea. Foreign bodies embedded in the lids without causing inflammatory reactions were not removed. Of 57 lid injuries only 14 required repair with sutures. The right eye was injured in 52.5 percent of cases, the left in 42.5 percent, and both in 5 percent.

Ray K. Daily.

Martin, W. O. Treatment and care of common eye injuries. *Jour. Med. Assoc. Georgia*, 1943, v. 32, June, p. 189.

The author believes that every physician should be able to render first aid for the most common types of eye in-

jury. He reviews briefly the anatomy of the eyeball and the treatment of common corneal involvements, including burns. He condemns the promiscuous use of atropine.

T. M. Shapira.

Michaelson, I. C., and Kraus, J. War injuries of the eye. *Brit. Jour. Ophth.*, 1943, v. 27, Oct., pp. 449-461.

Seven cases of double injury to the walls of the eyeball by foreign bodies are described. In six cases in which the fundus could be observed ophthalmoscopically, a solid, raised white mass was seen projecting into the vitreous at the site of the exit wound. Two of the cases which were examined histologically showed proliferated choroid tissue projecting into the vitreous through a gap in the overlying retina. The plugging of the retinal gap by the choroid reaction would appear to be purposive in nature, because only two cases showed detachment of the retina, in spite of large retinal holes. (14 illustrations.)

Edna M. Reynolds.

Mitskevich, L. D. Technique of suturing wounds of the lids. *Viestnik Oft.*, 1943, v. 22, pt. 2, pp. 46-47.

The author describes a figure-eight suture for repair of through-and-through wounds of the lids. This suture, which brings together the cartilage and conjunctiva, makes for better coaptation of the wound edges, and prevents overriding of the cartilage segments. In first aid to lid injuries careful débridement with immediate suturing is important. For good healing it is important to have no tension on the sutures, and this the author accomplishes by means of canthotomy. (2 illustrations.)

Pfeiffer, R. L. Traumatic enophthalmos. *Arch. of Ophth.*, 1943, v. 30,

Dec., pp. 718-726; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41.

Of 120 cases of fracture of the bones of the face in which the orbit was involved, enophthalmos was present in 53. Fracture of the orbit was observed in every case of traumatic enophthalmos during a period of ten years. All of the cases of traumatic enophthalmos uniformly showed roentgenographic evidence of a fracture of the floor of the orbit, with prolapse of orbital tissue into the maxillary sinus. In cases of severe enophthalmos the entire antrum was filled with orbital tissue.

The convex posterior portion of the floor of the orbit bulges upward back of the eyeball in a position to receive most of the force transmitted by a blow on the eye. As the floor is composed of very thin bone, it is easily ruptured, allowing orbital contents to herniate. Following such a displacement there is enophthalmos, often with disturbances in motility of the eye. Paresthesias of the face from fracture of the infra-orbital canal and rupture of the infra-orbital nerve are common.

Treatment may not be indicated unless the displacement is severe. Muscle operations have successfully overcome diplopia. The surgical correction of the enophthalmos is under study. Some attempt should be made to replace the inferior orbital wall and to prevent the herniation of orbital contents. The author suggests that patients exhibiting signs of recent contusion to the orbit be subjected to roentgenographic examination for possible internal fracture of the orbit. (2 photographs, 3 roentgenograms, 2 tables, bibliography.)

John C. Long.

Philps, A. S. The extraction of magnetic foreign bodies from the vitreous chamber of the eye. *Trans. Ophth. Soc.*

United Kingdom, 1942, v. 62, pp. 169-176.

The author describes the use of the magnet in removing foreign bodies from the vitreous through an opening made in the sclera.

The foreign body is localized with the use of the ophthalmoscope and X-ray, and if possible is drawn by a magnet into the area of the external rectus. The conjunctiva is opened and the external rectus muscle divided. A linear incision is made in the sclera after sutures have been placed, and the magnet is applied and the foreign body removed. The scleral suture is tied, the rectus muscle repaired, and the conjunctiva closed. Fifteen percent of the patients so treated showed vision of 6/12 or better; 11 percent, 6/18 to 6/60; 23 percent, finger counting and good perception; 50 percent, no light perception but the eye of normal size; 4 percent had shrunken eyes, and 42 percent of the eyes were lost. (4 illustrations.)

Beulah Cushman.

Pokrovsky, A. J. Characteristics of intraocular foreign bodies in military and civil injuries, and the technique of their removal. *Viestnik Oft.*, 1943, v. 22, pt. 1, p. 4.

This is a comparative study of 125 war injuries and 125 industrial injuries. The foreign bodies of war and industrial injuries differ in their magnetic properties. In industrial injuries 85 percent of the foreign bodies are magnetic. In war injuries 30 to 40 percent are nonmagnetic. An important characteristic of the foreign bodies in war injuries is their multiplicity and minute size. Not one of the industrial cases showed more than one foreign body; in the war injuries 15 percent of the eyes had several foreign bodies. In war injuries the foreign bodies penetrate

deeper into the posterior ocular segment, and may pass through the eyeball; double ocular perforations are therefore much more frequent in war injuries.

The operative data differed widely in the two types of injuries. In civil injuries, 70 to 75 percent of the foreign bodies were extracted within the first week after the injury. Because of the necessity of passing through several hospital stations the majority of war injuries were operated upon 20 to 70 days after injury. Of the industrial foreign bodies 82 percent were successfully removed with the electromagnet. Early in the war electromagnetic extractions were successful in 64 percent of war injuries. With accurate roentgenographic localization this percentage was increased to 72.

The author is an advocate of extraction through the sclera; he holds that extraction by this route is more often successful, and is followed by more rapid recovery and by less marked inflammatory reaction. The foreign body is less apt to be caught in the ciliary processes or iris, or to set up a cyclitis. The author uses prophylactic diathermy-coagulation of the sclera, which prevents retinal detachment and intraocular hemorrhage.

The delay in extraction of foreign bodies in war injuries adds to the difficulty of the procedure. After they become fixed in an exudate, they offer greater resistance to the electromagnet. To attract them with the greatest possible electromagnetic force they should be very precisely localized. This is possible only through close coöperation of ophthalmologist and roentgenologist.

Reese, A. B., and Khorazo, D. Endophthalmitis due to *B. subtilis* follow-

ing injury. *Amer. Jour. Ophth.*, 1943, v. 26, Dec., pp. 1251-1253. (References.)

Sudakevich, D. I. **Orbital prosthesis for the sequelae of war injuries.** *Viestnik Oft.*, 1943, v. 23, pt. 1, p. 25.

Protheses intended to replace losses of the facial tissues should be thin, small, and light, and should fit firmly to the face without interfering with movement of the facial muscles. This paper is an attempt to classify orbitofacial injuries for the purpose of determining the type of material suitable for a prosthesis. The author divides the injuries into orbital, orbitofrontal, orbitonasal, and orbitomalar. In orbital injuries the orbicularis oculi may be partially or totally destroyed. In partial destruction the muscle is contracted and will press on the edges of the prosthesis. In total destruction a soft prosthesis will have no support. Therefore prosthesis for orbital defects should be made of firm inelastic material. In orbitomalar injuries the prosthesis should be of soft pliable material, because cicatrices of the muscles of the face will tend to displace it forward and upward.

The orbitofrontal and orbitonasal injuries occupy an intermediate position between the orbital and orbitomalar. In orbitonasal injuries, contraction of the corrugator pulls the inner edge of the eyebrow down and in; the prosthesis should be firm, inelastic, and fastened to the bridge of the nose; and cases with destruction of the ala of the nose require elastic prosthesis.

Orbitofrontal injuries raise the eyebrows and upper lids, with frequent total destruction of the eyebrows. Destruction of the eyebrows and prominence of the upper margin of the orbit are indications for inelastic material to which can be fastened artificial eye-

brows. Extensive destruction of the forehead should be replaced by a pliable prosthesis. Ray K. Daily.

Treatment of eyes injured by mustard gas. *Brit. Med. Jour.*, 1943, July 24, p. 111.

The clinical picture of the eye injured by mustard gas has three stages: first, stage of impregnation; second, acute stage; third, stage of recovery. The onset is without any symptoms and the gas becomes impregnated in the eye without any pain or discomfort. This lasts one to three hours. The acute stage begins suddenly with hypersecretion of the conjunctival and lacrimal glands. Edema of the eyelids closes the palpebral fissure. This lasts from two to five days. In recovery, the edema of the lids slightly subsides but the lacrimal secretion and the photophobia persist. This may last for weeks or months.

Bonnefon, in the First World War, irrigated the eyes with a warm hypertonic solution containing sodium sulphate. Even in cases of very intense palpebral edema this solution enters the fissure and osmotic drainage can occur. The osmotic treatment should be continued as long as there is any photophobia and lacrimation. Cocaine must never be used, as it will cause damage to the corneal epithelium. Liquid paraffin and oily drops must not be used so long as there is any possibility of dichlorethyl sulphide remaining in the conjunctival sac, because they are solvents of this substance and may cause further damage.

SYSTEMIC DISEASES AND PARASITES

Allen, M., Flack, F., and Billings, M. L. **Three pedigrees of eye defects.** (Nystagmus and myopia.) *Jour. of Heredity*, 1942, v. 33, Dec., p. 453.

Two of the three short histories deal with hereditary nystagmus. The first includes case records of four school children.

The article "A familial study in myopia" discusses the presence and progress of shortsightedness in several families. Since all the patients included in the author's chart showed myopia before they were ten years old, he thinks it unlikely that use is a factor in the causation of this condition.

F. M. Crage.

Bellows, J., Cooper, J., and Bull, H. B. **Electrophoretic studies on serums of patients with ocular disturbances.** *Arch. of Ophth.*, 1943, v. 30, Nov., pp. 621-625.

The electrophoretic technique of Tiselius has been used by a number of workers to study the proteins in normal and pathologic human serums. In short, the components of a mixture of proteins are separated by their difference in mobility and the number and concentrations of the components determined.

Studies of serum proteins by earlier methods in cases of glaucoma failed to disclose abnormalities. In this paper the data obtained in electrophoretic analyses of the serums of 18 patients with various pathologic conditions are presented. The authors point out that for the most part the patients used in this study had other pathologic conditions associated with the ocular lesions.

The appearance of new protein fractions seemed to be a characteristic

observation in cases of chronic intraocular disease. This is thought to suggest that the pigment is the more important factor. Slight indications of the new fraction were found in the serum of patients with secondary glaucoma following extracapsular extraction and cortical cataract. (References, 1 table and 1 series of diagrams.)

R. W. Danielson.

García Miranda, Antonio. **Importance of the slitlamp in the study of starvation conditions.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, July, pp. 108-113.

This is stated to be a preliminary communication. In the many cases of starvation or undernourishment following the Spanish civil war, the author noted a conjunctival injection which under high magnification was found to be arranged in two plexuses, one superficial and the other deep. This conjunctival injection is taken to be the first ocular manifestation of avitaminosis-A, perhaps present earlier than hemeralopia. When the process is further advanced, the injection is less noticeable, because the conjunctiva is thickened and the conjunctival vessels are obscured by conjunctival opacities. The Bitot spots appear still later. These early signs are seen more particularly in the conjunctival area corresponding to the palpebral fissure, and above all toward the caruncle and semilunar fold as well as in the region of the sclerocorneal limbus. Administration of riboflavin produced retrogression of the vascularity. The author suggests that the resemblance between the condition he describes and some forms of pannus or of keratitis from acne rosacea requires further investigation. (2 illustrations, references.) W. H. Crisp.

Green, Raymond. The role of vitamins in ophthalmology. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 47-51.

From the general knowledge of vitamins and the author's own experience in polar expeditions he gives a table of the nature and source of the vitamins, the daily need, and signs of deficiency. He emphasizes that deficiency diseases seldom occur singly, and that deficiency may arise from deficient intake, deficient absorption, or increased needs of the body. A symptomless deficiency may carry on until some special condition arises, such as an injury or operation. Or the deficiency may be shown by undue susceptibility of the mucous membranes to infection. Fatigue is the symptom always found in frank deficiency. Beulah Cushman.

Harms, H. Interrelationships between the condition of the nervous system and the eye. *Med. Klin.*, 1942, v. 38, Aug. 7, pp. 745-749.

This somewhat diffusely written article touches upon many points of relationship between the eye and the general nervous system, including scotoma scintillans, unilateral amblyopia, retrobulbar neuritis, cerebral concussion, disturbances of the fusion apparatus, hysterical blindness and ophthalmoplegias, and glaucoma.

Pett, L. B. Riboflavin and vitamin A in relation to "eyestrain." *Canadian Med. Assoc. Jour.*, 1943, v. 49, Oct., pp. 293-295. (See Section 3, Physiologic optics, refraction, and color vision.)

Scobee, R. G. Ocular findings in feeble-minded male castrates. *Amer. Jour. Ophth.*, 1943, v. 26, Dec., pp. 1289-1298. (One table, references.)

Shapiro, A. L. Blindness and multiple neuritis from vitamin-B deficiency. *Med. Bull. Veterans' Admin.*, 1943, v. 20, July, p. 106.

A case of multiple neuritis and blindness due to alcoholism is reported, and the relation of the disorder to vitamin-B deficiency is discussed. The patient was receiving a regular hospital diet, apparently adequate as to vitamin B, yet no improvement was obtained until large concentrated doses of thiamine were given, intramuscularly. Despite the long period of time which had elapsed before improvement was obtained, the author remarks that complete recovery proved possible once adequate therapy was instituted. Alcoholic addicts are especially susceptible to vitamin-B deficiency.

Gertrude S. Hausmann.

Williamson Noble, F. A. The role of vitamins in ophthalmology. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 53-63.

A review of the literature is given. Vitamins in their crude form, such as vitamin A in cod-liver oil, are of more clinical value. Vitamins B and C are important in the metabolism of the cornea, the most important being riboflavin. Riboflavin cannot be synthesized by the cells of the body, and a continual supply from exogenous sources is re-

quired to make up what is lost in the urine and other excretions. Probably the metabolism of the avascular cornea is maintained by riboflavin. Corneal grafts are kept healthy by the cornea's own oxidative system independent of the blood supply. If this fails, the demand for hemoglobin results in corneal vascularization.

The lens seems dependent on the lactoflavin fraction of vitamin B. It does not, like the cornea, become vascularized if the enzymes are deficient, and it therefore degenerates. Vitamin C may provide the alternative means of respiration for the lens.

The deficiency of vitamins C, K, and P can be studied particularly well in the retina, as such deficiencies produce hemorrhages by various mechanisms. In vitamin-C deficiency, capillary hemorrhages are characteristic, arising from failure of the cement substance between the endothelial cells, and there is also a decrease in the coagulation time. Vitamin K, fat-soluble, is thought to combine with an unknown hepatic product to form prothrombin. Vitamin P probably has its action on the cell bodies of the capillaries, and increases their resistance to pressure. (Bibliography.)

Fox, S. A. *Optometry: a medical viewpoint*. Dis. Eye, Ear, Nose, and Throat, 1942, v. 2, Dec., p. 369.

The controversy between optometrists and ophthalmologists is discussed at length. Eventually optometry may "have to decide whether it is to be a skilled trade which purveys glasses or a profession devoted to eye treatment." One ophthalmologist feels that if optometry continues in its present course "the medical schools may find it necessary to absorb the teaching and control the practice of this profession." The increase in postgraduate medical study and consequent increase in eye physicians will force a decision. Closer relationship between the general practitioner and patient, which will cause the physician to refer the needy to the ophthalmologist, should help solve the problem of proper attention for eye troubles.

F. M. Crage.

Halliday, J. C. The causes of blindness in children. *Med. Jour. Australia*, 1943, v. 1, June 19, p. 556.

The cases admitted to the school for deaf and blind during the years 1911 to 1920 are tabulated. Optic atrophy, congenital cataract, and ophthalmia neonatorum seem to be the leading causes. Another summary several years later showed fewer cases of ophthalmia neonatorum. (2 tables.)

Gertrude S. Hausmann.

Harkness, G. F. Industrial ophthalmology. *Industrial Med.*, 1943, v. 12, Oct., pp. 658-662.

The author, in surveying lightly the fields of industrial ophthalmology and otolaryngology, stresses the fact of governmental responsibility in the conservation of public health, and the consequent need for adequate unification of state laws regarding compensation and conservation of vision. It is important for the ophthalmologist, in turn, to have a proper basis for evaluating visual efficiency, and to be familiar with the specific needs of those industries with which he is connected. The surgeon is an important figure in the safety program of each industry. In this connection, the ophthalmologist should be familiar with proper lighting conditions. Any uncertainty regarding the compensability of an eye condition should be resolved in favor of the employee. The surgeon likewise has a responsibility to his employer, and must constantly be on the alert for malingerers.

In considering corneal foreign bodies and minor eye injuries, the author emphasizes the desirability of X-ray examination in every case at all suspicious. The technique for removal of foreign bodies is described; the author

feels that an eye patch is not indicated in every case, and that the guiding factor should be the subjective symptoms. Conservation of man-hours of work is a most important consideration.

Kravkov, C. V. The significance of Newton's work in physiologic optics. *Viestnik Oft.*, 1943, v. 22, pt. 1, p. 3.

Kravkov credits Newton with being the founder of the physiology of color vision. In Newton's books on optics are found accurate descriptions of the refractive errors and of afterimages, and a correct conception of the crossing of the optic nerves at the chiasm. The relation of color perception to the physical properties of light was discovered first by Newton, who demonstrated that color differentiation was due to the varying refraction of the respective colored rays of light. On the principle of finding the center of gravity in mechanics, he designed a color circle with a method for determining the color resulting from various color mixtures.

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Clark, W. E. L. **The anatomy of cortical vision.** (Doyle Memorial Lecture.) *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 229-245.

As an anatomist the author is interested in the significance of the six-layer pattern of the lateral geniculate body. He obtained the brain of a monkey who had lost an eye in an accident some years before death. Later he was able to study the brain of a woman whose eye had been removed for glaucoma two years before death. In both instances the geniculate bodies showed exactly the same pattern of three layers receiving crossed fibers and the other three receiving uncrossed fibers. From these findings the writer became interested in following the projection of local retinal lesions on to corresponding local areas of cell atrophy in the nucleus, and he and his colleague Penman were able to determine the pattern of localization in the geniculate

body with great accuracy and to show that it represented point-to-point projection.

Transneuronal degeneration, which could be detected in the geniculate body one week after section of the optic nerve, might be indicative of an extreme specificity of function of the cells of the nucleus, and suggested to the author that the cells might depend entirely for continued activity on the reception of impulses from the retina, and that there were no other sources of afferent stimuli which maintained their vitality.

It was found that the optic nerves ended in the geniculate body in specialized ring formations, "terminal buttons." Degenerative reactions were demonstrable seven days after section, and direct proof was obtained that crossed fibers end entirely in laminae 1, 4, and 6, and uncrossed fibers entirely in laminae 2, 3, and 5. Each optic-nerve fiber ended in its appropriate lamina by dividing into 5 or 6 terminal branches, and each of these branches established connection with only one cell. It was also found that if the visual cortex of a monkey was completely destroyed all the nerve cells of the corresponding geniculate body appeared to undergo complete atrophy.

The three laminae for each eye also called for explanation, the lamination of the lateral geniculate bodies appearing abruptly during the sixth fetal month. One optic nerve of a monkey was sectioned. After time for degeneration of the optic fibers, sections of the optic tract showed no evidence of laminar arrangement, and it was only within the geniculate body that the retinal fibers sorted themselves out to reach their appropriate laminae. The author noted at this time that the smallest retinal lesion produced recog-

nizable changes affecting portions of all three of the corresponding cell laminae. He came to the conclusion that the conducting unit from the retina to the lateral geniculate body was a three-fiber unit. This supports the idea that the laminar pattern of the geniculate body may be related to trichromatic color vision. By means of the geniculate body, crossed and uncrossed retinal impulses are supposed to be brought into intimate relation with each other immediately on their

arrival at the cortex, thus providing for fusion of impressions necessary in stereoscopic vision.

Finally the author concludes that the geniculate body is a simple relay mechanism through which retinal impulses are immediately projected on to the visual cortex, and that there is no possibility that these impulses can be distorted and modified by other unrelated types of nervous impulse influencing the cells of the nucleus. (4 illustrations, references.) Beulah Cushman.

MISCELLANEOUS

The Department of Ophthalmology of the George Washington University School of Medicine will give its seventh annual postgraduate course in ocular surgery, pathology, and orthoptics, April 24 to 29, 1944, inclusive. This is a practical course, limited to 30 registrants. Surgery will be performed by the registrants on animal eyes. Ocular pathology will be illustrated with slides and by the use of the microscope. Orthoptic training will be taught

with cases and demonstrations. The fee is \$150.00. Further details will be furnished by the secretary, Miss Louisa Wells, 927 Seventeenth Street, N.W., Washington, D.C.

The Department of Otolaryngology of the University of Illinois College of Medicine announces its spring refresher course, to be held at the College in Chicago, March 20th to 25th, inclusive. The course is intended primarily for specialists who, under existing conditions, are able to devote only a brief period to postgraduate review study. The fee is \$50.00. Registration will be limited. In requesting application, state school and year of graduation; and give details concerning specialty training and experience. Address: Department of Otolaryngology, University of Illinois College of Medicine, 1853 West Polk Street, Chicago, Illinois.

One of our advertisers, the National Electric Instrument Company, was the recipient in November, 1943, of a star for its Army and Navy "E" award. National received its Army and Navy "E" award in February, 1943.

A gift of \$10,000 was given to the Department of Ophthalmology of the Medical School of the University of Kansas by Dr. Edward J. Curran of Kansas City, professor and head of the department of ophthalmology, to provide the necessary equipment and assistance for research in the department.

SOCIETIES

The third regular meeting of the Ophthalmological Society, European Theater of Operations, was held on November 13, 1943, in the sumptuous new Officers Club Auditorium at the Headquarters of the 8th Air Force. There was an attendance of nearly 100, including many flight surgeons and guests from Allied Services.

The group was welcomed by Brig. Gen. Malcom C. Grow (MC), Surgeon, U.S.A. Air Forces in this theater, and host, Brig. Gen. Paul R. Hawley (MC), Chief Surgeon, E.T.O., spoke briefly, commending the ophthalmic medical officers for being the first and most active group in this theater in organizing their specialty, and in publishing a journal. Four excellent moving pictures of ocular surgery were shown. Dr. S. A. Leader, one of Britain's leading authorities in the manifold application of new plastics in the field of medicine, gave a most instructive talk on this sub-

ject. In ophthalmology plastics are already invaluable in the production of prostheses and contact lenses, and will play an increasing role in the protection of the globe in severe burns, and in the construction of large prosthetic appliances for deformities of the face. Plastics can meet any requirement in consistency, color, form and radio-opacity, and can be made self-sterilizing. The morning program closed with an interesting discussion on "Macular degeneration of unknown origin" by Squadron Leader J. Doggart, R.A.F., and a consideration of "Ophthalmic surgery in the field" by Brigadier Sir Stewart Duke-Elder, Chief Ophthalmic Consultant, R.A.M.C. Sir Stewart described the problems, experiences, and lessons encountered by ophthalmic medical officers with British Forces in Africa and the Middle East. He emphasized that a man without needed glasses is as much a casualty as a wounded soldier. This problem would be more serious for the British than the Americans, because the former have used lower visual standards in their combat forces. He warned against too hasty and too numerous enucleations, and advised that every man with an open wound of the globe be regarded as a litter patient. He did not feel that an implant after enucleation was worth the trouble. Asked for a practical test for night vision to rule out malingering, he recommended ordering the soldier to cross, in the dark, a latrine trench across which there was a single plank. If he fell in, the night blindness was considered genuine.

After lunch, and a photograph of the group had been taken, Air Commodore P. C. Livingston, Chief Ophthalmologist for the R.A.F., gave an excellent talk on "Scototics." Commodore Livingston has for many years been a leader in research on night vision and its application to night flying. The factors involved are many, but the careful screening of night fliers, by such as his hexagon test, and their training in how to see best in the dark, and among searchlights, has proved its value manyfold.

Both the R.A.F. and the U.S.A.F. had exhibits of their ocular equipment for testing, and for use by fliers. Several patients from Moorfields Eye Hospital, London, were demonstrated. The last paper was entitled "Influence on ocular function of oral use of sulfa drugs," read by Major N. S. Rubin (MC), 8th Air Force, who with Capt. Carlisle E. McKee was host and had arranged the meeting.

At a short business meeting Commodore Livingston was elected the fourth Honorary Member of the Society, the others being Brigadier Sir Stewart Duke-Elder, Lt. Commander Edwin Dunphy (U.S.N.), and Sir Ian Fraser.

At the meeting of the Colorado Ophthalmological Society on January 15, 1944, a symposium on contusions to the eye was presented. The following papers were given: "The bony orbit," by Dr. W. T. Brinton; "Conjunctiva and surrounding tissues," by Dr. Samuel Goldhammer; "Anterior segment of the eye," by Dr. Leo Davis; and "Posterior segment of the eye," by Dr. Edna Reynolds.

The eightieth annual meeting of the American Ophthalmological Society will be held at The Homestead, Hot Springs, Virginia, on May 29, 30, 31, 1944.

The members are requested to send to the chairman of the program committee, Dr. Walter I. Lillie, as soon as possible, the titles and brief abstracts of such papers as they desire to present at the meeting before April 15th, to be incorporated in the call for the meeting to be sent out about May 1st.

At a recent meeting of the Indianapolis Ophthalmological Society, Dr. Paul G. Moore, assistant clinical professor of ophthalmology at Western Reserve University School of Medicine, spoke on "The end results following intraocular foreign bodies."

The Los Angeles Society of Ophthalmology and Otolaryngology appointed the following officers for 1944: president, Dr. M. E. Trainor; vice-president, Dr. Kenneth Brandenburg; secretary-treasurer, Dr. Orrie E. Ghrist; and committeewoman, Dr. Etta C. Jeancon.

PERSONALS

Among the members of the Philadelphia County Medical Society who were given testimonial certificates for having been in practice 50 years or more was Dr. Burton Chance, Sr.

Dr. William E. Bruner, professor emeritus of ophthalmology, Western Reserve University School of Medicine, Cleveland, celebrated his fiftieth year in the practice of medicine at a dinner on January 4th. He was presented with a silver tray engraved with the names of his guests, his associates at the eye clinic of the old Lakeside Hospital.

The Best Eyes Are by Gougelman

PERFECTED
Plastic
 ARTIFICIAL EYES
 CHEMICAL
 AND IMPACT
 RESISTANT

Eye socket secretions have little effect on Gougelman Plastic Eyes. Discoloration and roughness are unknown to these long wearing comfortable eyes.

Secretions of the eye socket are destructive to ordinary artificial eyes, but plastic eyes resist the corrosive effects of these secretions and do not roughen with use. Absent, also, is the discoloration, due to chemical reaction, so common in other materials. Plastic eyes keep the original delicate shading of the sclera.

Other superiorities of Gougelman Plastic Eyes include the higher polish obtainable and the freer movement under the lid due to the retention of fatty substances that give the material an "oily" surface. Patients welcome the knowledge that these eyes are practically non-shatterable and non-crushable. Accidents always happen at the most inopportune times, both socially and financially. Plastic eyes

may have a higher initial cost, but in time they are economical. Probably plastic's greatest advantage to eye physicians is their moldability to many delicate anatomical shapes that were impossible before.

Gougelman Plastic Eyes are the result of intensive research. Only after long testing was their announcement possible—the first major improvement since Pierre Gougelman set up shop in 1851. Only made-to-order plastic eyes are available, but we suggest you send for a copy of "Advantages in Plastic Artificial Eyes," that explains in detail their qualities and application. A new chart for ordering Plastic eyes is also available on request.

A NEW TYPE OF PIGMENT LINE IN THE CORNEA*

FREDERICK W. STOCKER, M.D., AND RONALD E. PRINDLE, M.D.

Durham, North Carolina

Many instances of unusual pigmentation of the cornea were observed and described before the slitlamp and the binocular microscope were developed. However, a more accurate knowledge of the conditions in which pigmentation of the cornea might occur and the layers in which the pigment might be deposited was not obtained until careful studies had been carried out with these instruments.

The following types of corneal pigment lines have been described.

1. Fleischer's ring in keratoconus.
2. Senile corneal line (Staehli).
3. Pigment line in pterygium (Stocker).
4. Pigment line in corneal scars; for example, interstitial keratitis (Hudson, Vogt, Hanssen, and others).
5. Kayser-Fleischer ring: pseudosclerosis (Wilson's disease).
6. Krukenberg's spindle.

The first three types present fine pigment lines that have been shown to be located in the very superficial layers of the cornea immediately beneath the epithelium. Vogt¹ and Grueninger² have demonstrated that breaks in Bowman's membrane must be considered the site in

which the pigment in a senile corneal pigment line is deposited. Stocker's³ findings in some cases of pterygium support this theory. These breaks seem to develop when a marked flattening of the cornea occurs, producing astigmatism against the rule, as in old age, keratoconus, and some cases of pterygium.

The fourth type of pigmentation, pigmentation in corneal scars, is not well defined as to its location in the corneal tissue. Often it does not form a distinct line but stains the cornea more diffusely and never has been described as extending from one limbus to the other. Hansen⁴ examined microscopically an eye with a corneal scar which *in vivo* had shown pigmentation in its central parts. He found the pigment to be located partly between the epithelial cells, but most of it was deposited between the epithelium and Bowman's membrane, within that membrane, and in the corneal stroma. It never was seen to be located intracellularly.

The Kayser-Fleischer ring in pseudosclerosis is entirely different in appearance from these fine lines. It is much broader, of a yellow reddish color, and the pigment is deposited on Descemet's membrane.

In Krukenberg's spindle and some re-

* From the Department of Surgery, Ophthalmological Division, Duke Hospital and Duke University Medical School.

Figs. 1 and 2 (Stocker and Prindle). Pigment line in the cornea. Fig. 1. Pigment line across cornea from the 7- to the 5-o'clock position.

Fig. 2. Slitlamp view of pigment line.

lated cases, as described by Weinkauff,⁵ the pigment also is located on Descemet's membrane.

Epithelial melanosis of the cornea as described in nevi of the limbus and in malignant tumors growing from the conjunctiva into the cornea, is excluded from consideration in this paper. Vogt,⁶ in his slitlamp Atlas, states that in some cases of nevi of the conjunctiva the pigment may invade the adjacent epithelium.

Concerning the nature of the pigment found in the various types of corneal pigment lines, the following observations have been reported: Fleischer⁷ proved that the pigment line in keratoconus is hemosiderin. It is probable that the pigment in the other three of the first four types hereinbefore mentioned is also of hematogenous origin. In his case of pigmentation of a corneal scar Hansen⁴ could exclude hemosiderin, but he had no positive suggestion as to the nature of the pigment. The pigment in the Kayser-Fleischer ring in pseudosclerosis is of an entirely different nature. According to Vogt⁸ finely dispersed silver seems to be present in most of the cases. Others have reported the presence of copper, zinc, and other heavy metals. In Krukenberg's spindle the pigment is believed to originate from the uveal pigment.

Pigment lines of the cornea are not only of theoretical interest but sometimes of diagnostic value. Therefore, any observation of a heretofore unknown type of corneal pigmentation should be reported. We have had the opportunity to observe a corneal pigment line that differs in several characteristics from all the previously described types.

CASE REPORT

L. F. W., 24 years old, a darkly pigmented Negro, was first seen in the Duke Hospital Eye Clinic in early November of 1941, complaining of a painful left

eye. Two weeks previously some "trash" blew into his left eye, which felt irritated for a few hours, but caused no further trouble until four days later when it became red and painful. At about this time he contracted a severe generalized Dermatitis venenata (*Rus toxica*). He believed that this precipitated his eye trouble. Treatment was with eye drops of an unknown character and various skin lotions.

When first seen his dermatitis had completely cleared but the left eye was causing him considerable discomfort. Vision O.D. was 20/30; O.S., light perception. The right eye was essentially normal. In the left eye there was a diffuse hyperemia of the conjunctiva with a rather marked circumcorneal flare. There was extensive brownish pigmentation of the limbus and adjacent conjunctiva. The corneal transparency was slightly decreased. The anterior chamber was deep, the pupil irregular, semidilated, and fixed. The fundus could not be visualized. The tension was slightly elevated. Slit-lamp examination revealed an intact epithelium and normal corneal stroma. There were many deposits on the posterior surface of the cornea, a prominent aqueous flare with numerous cells, and extensive adhesions between the iris and lens.

The family history, past history, and systemic review were noncontributory. Venereal diseases were denied and blood tests were reported as negative by his local physician.

The diagnosis of nonspecific uveitis with secondary glaucoma was made. Hospitalization was advised but had to be postponed for several weeks for financial reasons. He was treated in the meantime with atropine drops and hot compresses.

In December, hospitalization was arranged for a course of hyperpyrexia with

intravenous typhoid "H" antigen. Hot compresses and atropine instillations were continued along with the usual supportive therapy. Physical examination and laboratory workup, including serology and chest X-ray films, were negative. The eye objectively presented little change except for early cataractous changes in the lens. The tension had decreased to normal limits. Subjectively the eye had improved.

The patient was discharged with instructions for instillations of atropine 1 percent, the application of hot compresses, and cod-liver oil to be applied locally and taken orally.

Frequent return visits were impossible because of transportation difficulties. One month later the eye showed much less conjunctival and circumcorneal hyperemia, but there was beginning deep vascularization of the cornea, inferiorly. Keratic precipitates were still numerous and there was a dense aqueous flare. The pupil was unchanged. The condition of the eye had caused no further symptoms other than marked visual loss. Repeated search for a possible focus of infection was negative. During the following months the inflammation gradually subsided, but the infiltration and vascularization of the cornea progressed, especially from below.

Eight months after the first examination the first appearance of a fine brownish line was noted, extending across the cornea from the limbus at the 7-o'clock position to the opposite limbus at five o'clock (fig. 1, frontispiece). Slightly to the nasal side of the center of this line a delicate branch with the same appearance radiated diagonally upward. Grossly, this transverse pigment line appeared to be a continuation of the limbal pigment onto the cornea. Slitlamp examination (fig. 2, frontispiece) confirmed this and showed the pigment to be located in the

very superficial layers of the cornea. Under high magnification this line had a stippled appearance with a definite broad junction with the limbal pigment of the nasal side and a faint threadlike junction with the limbal pigment of the temporal side. There was a rather dense infiltration of the stroma of the lower half of the cornea with very deep vascularization. A faint aqueous flare was still visible but there were no cells. The pupil was slightly eccentric superiorly, oval in shape, and fixed. Tension was normal.

Thirteen months after the original visit the patient returned because of the recurrence of pain in the left eye. Examination was as before but the left eye was now blind. Enucleation with glass ball implantation was performed. Convalescence was uneventful.

The gross and microscopic examination of the enucleated bulbus revealed the following findings:

Gross examination showed a moderately shrunken bulbus. The lower half of the cornea was opaque. A brown pigment line was clearly visible, running horizontally from the nasal to the temporal limbus. Near the center of this line a branch extended upward.

Microscopic examination revealed the sclera to be thickened throughout, particularly on the nasal side of the posterior segment. From this area arose a mass of granulation tissue involving the inner layers of the sclera, the choroid, and the retina. A similar but smaller lesion was present on the temporal side. This tissue consisted largely of round and epithelioid cells with a few giant cells. In some areas there was caseation. The retina, in the regions which were not involved in the described process, was detached except for a narrow margin near the ora serrata. The ciliary body and processes were atrophic. The angle of the anterior chamber was obliterated by adhesions of the

peripheral margin of the iris to the posterior surface of the cornea. The pupillary margin was adherent to the anterior lens capsule. The iris showed considerable round and epithelioid-cell infiltration.

At the limbus, the corneal epithelium

cells and in places round-cell infiltration. A few small blood vessels could be seen in the stroma, but no connection of the pigmentation with the vascularization could be demonstrated.

In accordance with the direction in

Fig. 3 (Stocker and Prindle). Section through cornea, high magnification. E, epithelium; B, Bowman's membrane; S, stroma. Arrows show pigment located in epithelial cells.

appeared thickened. The cells in the basal and medial layers contained considerable brown pigment. The architecture of the corneal epithelium was not markedly disturbed and showed the normal arrangement of a basal layer of cylindrical and cuboidal cells and a superficial layer of flattened cells. In a small area near the center of the cornea, the basal cells contained large brown pigment granules. Small amounts of this pigment were seen in a few of the superficial cells (fig. 3). It had the same appearance as the limbal pigment. It did not react to iron stain. The corneal thickness was about normal. There was an increase in the number of

which the eyeball was sectioned, this pigment area must be identical with the pigment line observed macroscopically. Bowman's membrane was intact throughout. No pigment was found on, in, or beneath this membrane, nor in the stroma.

The pathologic picture was most suggestive of tuberculosis, although no tubercle bacilli were demonstrable.

The pigment which was found in the corneal epithelium was not hemosiderin, as in Fleischer's ring, since it did not stain by the Berlin blue method. Most probably it was melanin, since the corneal pigmentation was continuous with the pigment of the limbus.

DISCUSSION

How does this melanotic pigment establish itself in the corneal epithelium and why does it form such a very fine line instead of invading the cornea diffusely? It is well known that, in the Negro, inflammation is commonly associated with abundant pigment formation. Therefore, the appearance of pigment in the cornea, which to a certain extent was involved in the extensive inflammatory process of the whole eye, is not surprising. Why the pigment does not invade the cornea diffusely or along the blood vessels is more difficult to explain. The horizontal senile line and the line seen in pterygium could be explained by a flattening of the cornea in one direction, causing a break in Bowman's membrane. Since in our case the pigment was located in the corneal epithelial cells, and Bowman's membrane was intact, this explanation would not apply. As the principal pigment line in our case was located in the palpebral fissure where light had the most access to the cornea, the hypothesis might be advanced that the melanin was formed

by the action of irradiation on some premelanotic substance originating from the inflammatory process. Unfortunately, we were not able to test the dopa reaction, which might have thrown some light upon that problem, for we were unable to get the necessary reagents.

SUMMARY

1. A previously undescribed type of corneal pigment line is reported in the eye of a Negro which had been the site of a severe inflammatory process, probably tuberculosis.

2. The pigment has been demonstrated histologically to be located within the corneal epithelial cells. Bowman's membrane was intact throughout and both this membrane and the corneal stroma were free of pigment.

3. The pigment does not take the iron stain and is considered to be melanin.

We are indebted to I. N. Dubin, M.D., of the Department of Pathology, for his technical assistance in the preparation and sectioning of the eyeball.

AN OPHTHALMOLOGIC REVIEW OF MORE THAN TWENTY THOUSAND MEN AT THE ALTOONA INDUCTION CENTER

L. P. GLOVER, M.D., AND WILLIAM R. BREWER, M.D.

Altoona, Pennsylvania

The opportunity to study a group of 21,446 men examined at the Altoona Induction Station, over a period of months, gives a rare picture in the eye findings in young men between the ages of 17 and 44 years, as found in central Pennsylvania. These men were examined in daily order, no attempt being made to select a particular group. Such a record could not be obtained from a study of cases coming into the office, for the patient who makes an appointment with an ophthalmologist usually suspects a need of visual correction, or has some ocular disease. Five thousand of the men between the ages of 17 to 21 were classified separately, in an effort to determine if the younger men had any marked variation in percentage of eye defects. The record does not show this to be so. Consequently, the discussion covers the group as a whole.

The men are from the counties of Blair, Bedford, Clearfield, Centre, Cambria, Sommerset, Indiana, Huntingdon, Mifflin, and Clinton. This area represents an ideal cross section of Pennsylvania, for at least five of the counties contain very few foreign born or children of foreign-born parents, whereas the remainder of Pennsylvania has a high percentage of this stock. Farming, coal-mining, heavy-metal, and other types of industry are about equally divided; only four cities have a population of over 10,000.

In this review only men with 20/40 or less vision were considered, as this was the army standard for acceptable vision. There were many others whose vision ranged from 20/40 to 20/20. In this age group hyperopia is not fairly shown, for the men still have active accommodation. Naturally, only those with high errors of

hyperopia have 20/40 or less vision.

Aphakia was not listed, but the eye, if aphakic, was placed under the heading of congenital or traumatic cataract as originally acquired.

Corneal scars were considered only if a loss of vision to 20/40 or less was present.

Refractive errors led in cause of defects, with 16.07 percent. We were unable to find that the family status had any bearing as a causative factor. Diet apparently was not a factor, as rich or poor appeared to be equally affected with myopia, squint, and amblyopia. The children of old American stock seemed to have a higher incidence of myopia as compared to those of foreign parentage. Amblyopia was no respecter of nationality. High hyperopia was found more frequently in the Italian.

We were surprised at the figures for amblyopia without squint, for 2.39 percent were amblyopic and only 0.75 percent of these had squint. Amblyopia in this study is 20/70 or less vision, corrected. We had thought from our office practice and reading that amblyopia is more frequently associated with squint. The findings do not substantiate our idea of this relationship.

Many of the men who had refractive errors, had never had glasses, and an equal number had glasses and would not wear them. This examination definitely shows that a young man, unless willing, does not wear glasses, and apparently no amount of education can change his mind. Men with high errors of refraction frequently had left their spectacles at home or wore them in their pockets. Others had never troubled themselves to obtain

glasses, and, in many instances, not through lack of funds, as agencies furnish glasses throughout most of these counties. A surprising number of men were wearing from plano to plus 0.25D. sphere.

Congenital defects (omitting amblyopia) were only 0.43 percent, congenital cataract being the leader with 0.144 percent. These figures were not excessive and speak well for this group.

Traumatic injuries are the disgrace of childhood; they are in many cases the result of carelessness, usually in the home. The history of injury with scissors, knives, air rifles, and arrows, all too well explains the traumatic cataracts or enucleations. No industry would permit such an appalling figure among so relatively small a group. In fact very few of these men obtained their ocular injury in industry. We are at a loss as to the best educational method to suggest in preventing this waste of sight. A mother with many children cannot always watch what a child is doing, but it is certain that scissors and knives should not be among accepted children's toys. Apparently surgical care of these cases has been adequate and well done.

Among the ocular diseases blepharitis, conjunctivitis, and chalazia were very low. The chorioretinitis and uveitis cases were the usual focal-infection type and comprised 0.456 percent. Often these men

had never seen a physician, or, if treated, had in many instances poor medical care, as no search for focal infection had been made. This is particularly true of the rural population.

History of trauma could seldom be obtained in the detachment cases, so they were listed under acquired diseases. Only one case had a history of operation.

Five cases of toxic exophthalmos was rather high among this age group; two of these men had been operated upon. As compared with office practice the number of cases of interstitial keratitis was low. Optic atrophy was frequently associated with chorioretinitis. Retinitis pigmentosa was probably higher than is here shown, for an eyeground study was not made in all cases.

The cases of familial macular degeneration were in brothers. The number of cases of myopic chorioretinitis, 0.884 percent, was high, but this would naturally be expected as the number of men with high myopia was large.

CONCLUSION

Of 21,446 men going through the Altoona Induction Station, a total of 21.36 percent had eye defects that lowered vision to 20/40 or less. This, excepting hyperopia, represents a fair cross section of eye defects in central Pennsylvania.

1200 Fourteenth Avenue.

THE FORM AND CHARACTER OF ROD SCOTOMETRY

P. C. LIVINGSTON, AIR COMMODORE, O.B.E., A.F.C., F.R.C.S., F.R.C.S.E.
London W.1, England

Dark-room field testing is not in itself new. The method in the main has aimed at excluding extraneous effects likely to induce attention waver. Detailed consideration does not appear to have been given to the encouragement of rod response only, while calling upon the cones to fulfill the role of central fixation. So far, instruments have appeared designed with controlled sources of electric light for fixation object and for target. It is not easy to obtain a lighted target of a value that lies safely below cone threshold. A mechanism involving rheostatic control with the addition of filters is then necessary to influence both the luminosity and the color temperature. As complications multiply, so does expense increase and mobility become restricted.

To circumvent these difficulties, an alternative method has been sought, with a view to obtaining freedom from mechanical adjustment. Anticipation on the part of the patient, such as is encouraged by the rattle of cogs and the exactness with which the target arrives over the various areas, tends to produce an artificial atmosphere and restrict freedom on the part of the operator.

The problems that surround night vision have provided numerous avenues of approach. In the present instance it was believed that, in the dark-adapted retina, results might be achieved outside the range of standard procedures. Under the usual conditions that surround perimetry or scotometry, the hands of the examiner even though covered with black gloves, cannot be perfectly obscured. The unavoidable differences in background brightnesses between target holder and screen; shadows; the uncertainty regard-

ing the exact point of appearance of the target, all influence the eventual records. As so frequently happens, these influences become more significant when it is of special importance to obtain accurate evidence regarding the nature of a suspected defect while in its earliest stages of development.

The introduction, in the Ophthalmic Department of the Royal Air Force, of self-luminous targets for visual tests in absolute darkness dates from 1935. At that time, attempts were made to learn the extent of form recognition adjacent to the fixation point as compared with form perception divorced from analysis. The conditions of illumination of the objects for identification varied between 0.0002 e.f.c. and 0.5 e.f.c. The self-luminous discs for these experiments were employed for purposes of fixation and were thus a little above cone level. These were moved over an arc at the center of which was a circular frosted-glass screen of 2-inch aperture, in which silhouettes of varying character, such as aircraft, ships, and crosses could be exposed for recognition.

Later, in 1940, work was commenced in which luminous objects now at rod level became the targets, while a red light, the luminosity of which carried well into cone function, acted as the point of fixation. Thus, a system of scotopic scotometry developed. The scope for this technique within the realm of clinical ophthalmology now becomes of widening significance.

APPARATUS

The apparatus at this stage of development, consists of a one-meter Bjerrums screen, suspended from a central metal

pole. It is fixed in a strong frame that allows it to be firmly and evenly stretched in all directions. This facilitates the passage of the pins through the cloth without disturbance of the position of the screen. The side of the screen facing the patient is marked out in dots of white and red paint. The white dots indicate each degree and pass in a fan divided into 10-degree sectors from the fixation point to the periphery. The red dots run in circles around the fixation point and appear every five degrees. Such an arrangement simplifies the transfer of the record to the scotoma chart. As the test is carried out in complete darkness no adverse effects occur from the presence of the large number of dots. The fixation point is provided by a red light, from a 4-V dry-cell battery fitted to the stand. The bulb is set in a light-trapped black metal tube, so that, when burning, there is no escape of light except through the aperture providing the fixation point. By a suitable system of baffling, the pencil of light is lost to sight should the fixating eye commence to wander, a fairly common experience in dark-room studies of visual function. Refixation after wandering is readily encouraged. Provision is made for the adjustment of the height of the fixation tube so that each subject can be seated with eye height accurately adjusted to the pencil of red light. The character of the red light is important. It should be represented by a 1-mm. pencil shining through a rather deep-red filter approaching Wratten 89A. In trapping the source of the fixation light so that no movement of the field margin can come about, it is important to exercise care in the design of the tube baffles and also to employ for the chosen color a form of red that is attractive to the cones, but exercises the least possible effect upon the rods. Traquair's target holder was modified so that a target could be fitted to either end. It was also

strengthened, and metal caps were made to cover the self-luminous targets when they were carried through lighted rooms. This modification permits suitable freedom of movement by the operator. The self-luminous targets are composed of radium paint treated with varnish so as to vary the candle powers. The expression "candle power" seems rather overwhelming in view of the infinitely reduced power of the light source, but after due consideration it was voted the best form of expression. A suitable range of luminosity for screen testing is found to lie between 6×10^{-9} and 40×10^{-9} candle power in sizes of 1, 2.5, and 5 mm. The targets must be kept in the dark. Should exposure to light take place, a change in brightness occurs and the work should be postponed until the target has been replaced in darkness for one hour. The life of these targets without appreciable alteration in brightness can, it is said, be counted in years. For plotting, colored glass-headed pins are employed, so that when two or three tests are undertaken during the same period of darkness, no confusion arises during transfer of the record to the chart after the room light is turned on.

PREPARATION AND TEST

For this test to be of value, it is essential that the room in which it is conducted can be made completely dark. First, a routine screen examination is carried out in daylight. It is then explained that the principle of the test will be repeated in darkness, that a red light will substitute the white fixation spot, and a self-luminous target will replace the white test object. The subject wears dark neutral adaptation goggles of a light transmission of 3 percent (fig. 1). Adaptation is carried on for 30 minutes, and there is an added period in the dark room of 5 minutes to accustom the patient to the situation. It is

Fig. 1 (Livingston). Showing the patient's adaptation goggles on the left, the operator's goggles on the right, the test holder with two radium targets, a standard series of targets in folder, and two fields of vision. The fields here shown resulted from the examination of a case of papilledema. Note the considerable increase in the size of the blind spot (black) when examined in the dark, compared with the blind spot (crosses), by daylight testing. The dark method has revealed a spread in the exudate.

better, although not essential, for two operators to work together plotting the field, one moving the target the other marking with the colored pins. By this procedure, a minimum of disturbance takes place and the operator with the target can devote his time to concentrating upon the field area according to the nature of the case before him. The operators should prepare by adapting behind red goggles in which a neutral filter has been incorporated. The light transmission is approximately 4 percent. Red-neutral goggles are useful as they permit more latitude of movement during adaptation and do not prevent work being continued. Fifteen minutes of adaptation suffices, because full stability is not required by the operator, as with custom much skill in picking up the target, using wide eccentric fixation, can be acquired. The trick of fixating about 15 degrees away from the target soon becomes a habit. It is rarely found that the patient ex-

periences difficulties. The target should be moved slowly and steadily. A check upon the patient's attention and understanding can be provided by turning the target over, thus extinguishing the source of light. This effect is much more absolute than is experienced with the daylight technique. The margins of perception are sharp, so that the point of loss and reappearance of the target can be verified without any need to change the original pin positions.

RESULTS AND INTERPRETATIONS

Physiologic features. Targets below cone threshold produce a central scotoma, the area of which is normally enclosed within a circle of 2 to 3 degrees. It is sometimes found that the scotoma is oval or egg shaped, with its major spread lying in the horizontal axis (fig. 2). The blind spot is always larger than that recorded in daylight. The explanation, no doubt, lies in the state of myelination of

Fig. 2 (Livingston). This field exhibits the characteristic features found in normality at ground level. These are: (a) egg-shaped central scotomata, long axis, horizontal; (b) increase in blind spot over that found by daylight test; (c) presence of area of increased rod sensitivity indicated by dots; (d) triangular scotoma apex down lying between 70 degrees and 95 degrees, 23 degrees from the fixation point.

Test objects: 2 mm. white; 2 mm. self-luminous; brightness = 0.000000007 f.c.

Crosses = ground level, lights on; solid black = ground level, lights off, after 45 minutes dark adaptation; dots = area of rod hypersensitivity. Vision 6/6 6/6; date January 12, 1943.

Fig. 3 (Livingston). The effect of anoxemia upon a resistant subject. Observe the slight increase in the size of the blind spot and also the central scotoma. Compare this with figure 4.

Test objects: 2 mm. white; 2 mm. self-luminous; brightness = 0.000000003 f.c.

Crosses = ground level, lights on; solid black = ground level, lights off, after 50 minutes dark adaptation; cross-hatching = at 17,000 feet, after 35 minutes at that altitude. Vision 6/6 6/6; date February 24, 1943.

Fig. 4 (Livingston). The effect of anoxemia upon a normal but susceptible subject. Note the brief period of 15 minutes at 17,000 feet which has revealed an extensive contraction. Compare this with figure 3 when the subject was exposed for 35 minutes at the same altitude, and revealed no peripheral contraction.

Crosses = ground level, lights on; solid black = ground level, lights off, after 50 minutes dark adaptation.

Test objects: 2 mm. white; 2 mm. self-luminous; brightness = 0.000000003 f.c. Vision 6/6 6/6; date February 3, 1943.

the nerve fibers at the disc. As the stimulus is extremely delicate it fails to excite a reaction which would be elicited in the light. If a very small target of say 7^{10-9} candle power is employed, it is found possible to plot the course of the chief retinal vessels. To effect this, the target is passed backward and forward across the vessels, with a slow movement of narrow amplitude. Toward the periphery of the screen, a scotoma appears in about 20 percent of cases. This begins above the fixation point, starting some 20 degrees out; it is triangular in shape with its apex pointing downward. This may be regarded as representing a remnant of the secondary optic vesicle in which no abnormal ophthalmoscopic appearances can be observed. An area of high rod sensitivity is found 12 to 18 degrees outward and upward. It has been shown to coincide with histologic patterns, which are reported by Østerberg to form a more or less complete ring about the macula. This

Fig. 5 (Livingston). The field in an early stage of vitamin-A deficiency, showing defects in the form of paracentral contraction combined with enlargement of the central scotoma. Test objects: 2 mm. white; 2 mm. self luminous; brightness = 0.000000013 and 0.000000006 f.c. Crosses = normal blind spot, day, 2 mm. white; solid black = central scotoma, peripheral contraction, target 0.000000006; dots = insensitive over whole area, target 0.000000013.

Fig. 6 (Livingston). A diabetic subject since 1939—insulin until 1942—now on restricted carbohydrate diet. Sugar 1+.

Field of vision ground level, shows two characteristic small circular scotomata. The third and larger scotoma may be associated with the congenital closure defect described in the text. At 15,000 feet after 15 minutes, a relatively big contraction of the field of vision is revealed. This is considered quite abnormal for the altitude and exposure time recorded. The majority of diabetic subjects are more susceptible to anoxemia than are normal subjects.

Crosses = ground level, lights on; solid black = ground level, lights off, after 45 minutes dark adaptation; cross hatch = at 15,000 feet, after 15 minutes at that altitude.

Test objects: 2 mm. white; 2 mm. self-luminous; brightness = 0.000000003 f.c. Vision 6/6 6/6; date June 17, 1942.

zone of hypersensitivity encircles the fixation point.

Physio-pathologic features. A contraction of the field with an enlargement of the macular scotoma and blind spot, is found in anoxemia when brought about in the low-pressure chamber (fig. 3). Changes in the field become evident after 20 minutes at an altitude of 17,000 feet. The reaction is a delicate one with a wide variation between different subjects (fig. 4). Defects, in the form of paracentral contraction, combined with enlargement of the central scotoma, may appear at an

OCULAR ROSACEA AND ARIBOFLAVINOSIS

WINIFREDE M. FISH, M.R.C.S., L.R.C.P., D.O.M.S.

Oxford, England

Coincidentally with the publication in this Journal of Wise's thesis on "Ocular rosacea"¹ comes a further contribution to the subject from Conners, Eckardt, and Johnson.²

Wise's researches into the etiology of this disease cover a wide field, whereas the investigations of the Cleveland group are mainly confined to the biochemistry of riboflavin, its excretion by rosacea subjects, and the treatment of such cases by vitamin B₂ therapy, although in previous papers they have published statistics of gastric analyses³ and touched upon the possibility of a Demodex factor in ocular rosacea.⁴

On almost all points the findings of Wise and of the Cleveland group are diametrically opposed; two points, including one of fundamental importance, are mentioned by neither. It is on this point—namely, the type of corneal vascularization found in ariboflavinosis⁵ and not found in ocular rosacea—that a series of clinical investigations carried out by the present writer⁶ may fill a gap. Incidentally, they demonstrate the other point omitted by Wise and the Cleveland investigators; namely, that, at least in Oxford, rosacea is characterized by a marked seasonal incidence.

During routine slitlamp examination of sections of the population of England with the Oxford Nutrition Survey in 1942, although some cases of ariboflavinosis were found, there were none of ocular rosacea; but at the Oxford Eye Hospital the "rosacea season" was just beginning, and all such patients were examined with the slitlamp. They were divided into two groups, unilateral and bi-

lateral, in order to obtain, in the former group, a control eye per patient in which to look for the type of corneal vascularization constant in ariboflavinosis, unmasked by corneal infiltration or ulceration.

It was assumed that if ocular rosacea were the direct result of riboflavin deficiency, as stated by Johnson and Eckardt, these rosacea patients would show the specific type of corneal vascularization characteristic of ariboflavinosis. This is always bilateral, though not always equally advanced in both eyes; it is always symmetrical—that is, it invades the whole circumference of the cornea in both eyes, although, owing to the sclerocorneal "overlap" in the segment of the cornea covered by the upper lid it is rarely conspicuous there; it forms a more or less regular pattern of very fine, streamerlike superficial vessels which proliferate from the limbic loops of the pericorneal plexus and unite to form new tiers or arcades in the clear corneal substance, sometimes encroaching almost to the pupillary area. This stage is best seen by retroillumination. Circumcorneal injection is frequently absent until a late stage, when deep vascularization and corneal opacities may appear, with, in some cases, iritis. The picture in an early stage is entirely unlike that of ocular rosacea with its irregular, localized infiltrates that progress across the cornea just ahead of a leash of vessels and separated from them by a clear space. In later stages of both conditions the deep vascularization may be the result of secondary sepsis, but in the only two severe cases of ariboflavinosis seen in Oxford the corneal opacities

TABLE 1

SLITLAMP EXAMINATION OF 45 CASES OF DERMATOLOGIC ROSACEA

	Unilateral Ocular Rosacea	Bilateral Ocular Rosacea	No Ocular Rosacea
Corneal vascularization, B ₂ type, present.	0	0	1(a)
Corneal vascularization, B ₂ type, absent.	40	3	1(b)

Corneal vascularization, B₂ type = the bilateral, symmetrical type found in ariboflavinosis (with or without the irregular, localized type found in ocular rosacea).

were symmetrical, and there was much less local vascularization than would have been present in ocular rosacea of this degree.

Table 1 shows the result of slitlamp examination of 45 cases of dermatologic rosacea, in 43 of which there was ocular rosacea.

Of these 45 cases only one—case 1(a)—showed the B₂ type of vascularization. In this case, although there was mild cutaneous rosacea, there was no ocular involvement from it. Within a month, the cornea became almost normal on B₂ therapy, the new vessels being visible only as "ghosts." The cutaneous rosacea was unaffected.

Case 1(b) showed slight cutaneous rosacea without any corneal or other ocular abnormality and was not treated.

INCIDENCE

Seasonal incidence. Spring and early summer brought 42 cases under observation, midsummer only 1, and autumn, 2.

Sex incidence. Of the 45 patients, only 2 were males.

Age incidence. The youngest patient was 24 years old, the oldest 76. The average was 45 to 55 years.

THERAPEUTIC TEST

After slitlamp examination 20 of the patients were taken at random and divided in two groups, 10 in each. Group A received riboflavin only. Group B received routine treatment without riboflavin. Subsequently group A, having failed to respond to B₂ therapy, was given routine treatment in addition to riboflavin. The 23 remaining patients in group C received routine treatment and riboflavin, as shown in table 2.

The rate of healing varied with the severity of the lesion rather than with the age of the patient, although naturally most of the severe cases were among the older patients, owing to previous attacks of keratitis. These were the cases most prone to secondary sepsis. The addition

TABLE 2

RESULTS OF TREATMENT OF 45 CASES OF DERMATOLOGIC ROSACEA

Number of Cases	Treatment	Response
10 Group A	Riboflavin only	No improvement or exacerbation
10 Group B	Routine only	Healed
10 Group A	Routine and Riboflavin	Healed
23 Group C	Routine and Riboflavin	Healed
1 (a)	Riboflavin only	Healed
1 (b)	None	None

of riboflavin to routine treatment did not increase the rate of healing.

Probably the deprivation of mydriatics and antiseptics under test conditions accounts for the exacerbations in group A when on riboflavin only, although Johnson and Eckardt state that ocular rosacea clears up within four days on riboflavin. On the other hand, Wise found no improvement after very large doses of vitamin B₂ administered both orally and intravenously over periods of some six weeks or more; on the contrary, some of the lesions flared up. The Oxford patients received 9 mg. of riboflavin orally per day for one or two weeks—until, in fact,

it became apparent that it would be unwise to risk further deterioration of the cornea by depriving them of other treatment. Cases of ariboflavinosis—apart from rosacea—do not often respond promptly to B₂ therapy when, although mild, they are of long standing, but exacerbation during treatment is rarely if ever seen.

Routine treatment for ocular rosacea consisted of mydriatics where indicated, antiseptic lotions or drops for the eyes, dark glasses, sulpho-calamine lotion for the skin, dilute hydrochloric acid to be sipped with meals in cases suspected of gastric dysfunction, and, in selected cases,

CONCLUSIONS

Wise, New York	Johnson & Eckhardt, Cleveland	Fish, Oxford
Ocular rosacea follows facial rosacea and both are manifestations of the same disease.	The incidence of rosacea keratitis without acne is so much greater that the occurrence with it is now considered almost a coincidence.	Same as Wise.
Rosacea is not a manifestation of riboflavin deficiency.	Rosacea keratitis is the direct result of riboflavin deficiency.	Same as Wise.
Except in . . . rare cases . . . most of the distressing symptoms and sequelae of ocular rosacea are due to secondary infection with staphylococci.	(There is) absence of the bacterial conjunctivitis which is said to be the initiating factor in catarrhal ulcers. ⁷	Same as Wise.
The secondary infection in ocular rosacea can be controlled in almost all cases with a 5-percent sulfathiazole or sulfadiazine ointment used several times a day.		The secondary infection can be controlled by 10-percent albucid drops applied locally three or four times daily.
Rosacea probably is due to some factor causing vasodilatation in the facial area.		Same as Wise.
	The triangular characteristic of the superficial capillaries remains as the sole differential criterion. ⁷	The triangular area of vascularization is characteristic of ocular rosacea but not of ariboflavinosis, nor is the B ₂ type of vascularization present in rosacea.
Very large doses of riboflavin were given, in some cases over lengthy periods.	In addition to riboflavin, vitamin-B-complex was given, one teaspoonful of which contains therapeutic amounts of the whole B complex. Eggs, liver and milk were added to the diet.	Riboflavin was given only in a series of controlled cases. No special diet nor other treatment of any kind was given to these 10 patients in Group A until exacerbation became dangerous.

peritomy, tonsillectomy, or meibomian massage through the lids; 10 percent albugid (sulphacetamide) drops are now being used with good results, and treatment for seborrhoea capitis given in some cases.

All the Oxford patients had cutaneous rosacea but only one of them, case 1(a), appeared to be on a B₂-deficient diet; many were farmers and had more milk, butter, eggs, and vegetables than the average citizen. In the Cleveland series of 36 patients only 9 had "some cutaneous type of rosacea," and 34 were on a diet deficient in eggs, liver, and milk. Only one of the Oxford patients, the oldest, had iritis. The youngest patient, with a refractory case, did well after tonsillectomy. Three of the worst cases had recurrent meibomian infection and derived great benefit from meibomian massage; staphylococci were present in the expressed secretion, but no Demodex were found. Two very severe cases, both unilateral, required repeated peritomy. All the patients reported exacerbations when the eyes became sticky and secondary infection was obvious.

It seems probable that, in the Cleveland series of cases, the beneficial results attributed to riboflavin may have been due to the combined effect of all the constituents of the B-complex together with generally improved diet.

Biochemical research in the concentration of riboflavin in ocular tissue⁸ leads one to expect improvement in ocular rosacea from B₂ therapy, but neither slit-lamp examination nor therapeutic tests confirm the claim that this disease is due

to a deficiency of riboflavin.

Note: J. H. Duggart, in a paper on "Ocular rosacea" (Trans. Ophth. Soc., 1930, v. 1, pp. 98-109), describes an "encroachment of conjunctival vessels for a varying distance in the cornea, not only in the situation of definite infiltrates, but around its whole circumference," and figure II, reproduced in Duke-Elder's Textbook of ophthalmology, v. II, p. 1724, shows the typical corneal vascularization of ariboflavinosis with superimposed ocular rosacea. I have never seen both these types of vascularization, as thus depicted, in the same eye.

I should like to express my appreciation of the help given in this work by Prof. V. P. Sydenstricker, of the Georgia School of Medicine, Augusta, Georgia, who examined seven of the cases, including case 1(a); Miss Ida Mann, Mr. A. C. L. Houlton, and other colleagues at the Oxford Eye Hospital; Mrs. Pirie, of the Nuffield Laboratory, Oxford Eye Hospital; Dr. Hugh Sinclair and colleagues at the Oxford Nutrition Survey; Dr. Alice Carleton, of the Department of Dermatology, and Dr. Roy Vollum, of the Department of Bacteriology, Radcliffe Infirmary, Oxford.

I am indebted to Dr. V. P. Sydenstricker for the information that ocular rosacea is a rare disease in the southern states of America, whereas ariboflavinosis is—or was—not uncommon there; also for kindly correcting the proofs of this paper.

THE PSYCHOGENIC COLOR FIELD

JAMES E. REEDER JR., CAPT. (MC), A.U.S.
Modesto, California

Color fields have been used for some time in relation to organic disease of the eye, but the purpose of this article is to show that they have a possible application in the field of psychosomatic medicine. Traquair and Peter have shown that in certain types of individuals form fields may be either restricted, or of the spiral type. But the present writer has not seen a report of the application of color fields

to those who have a psychogenic factor.

As already mentioned colors are sometimes used to determine the extent of lesions of the retina and nerve. For example, in retinal detachments there is a loss of the blue field, especially in the area of the detachment, while in the diseases of the optic nerve the red field is either restricted or the color is not seen.

In the neurasthenic patient there is, a

Fig. 1 (Reeder). Normal form and color field. The sizes of targets for the field in the four figures presented are 2/330 for the form, 5/330 for the color fields. Dots = blue; dot dash = red; dash = green.

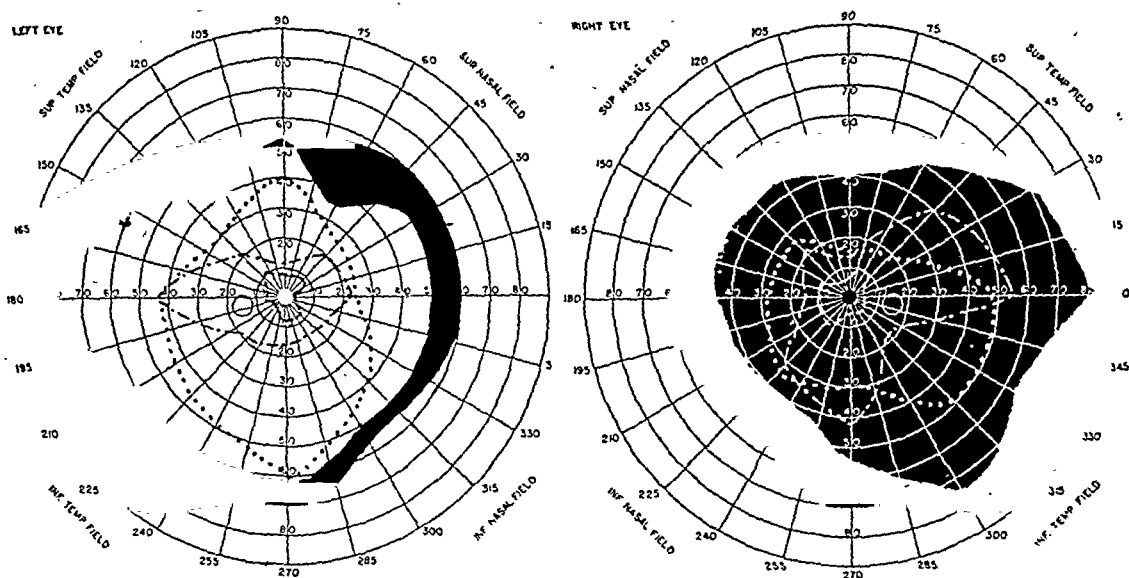

Fig. 2 (Reeder). Psychogenic field, mild.

change in the way the colors are arranged, and also in the size of the field of colors. The normal field for form and color is as shown in figure 1. As one can see, there is a wide range of even monocular vision. A normal color field will show the same contour as the form, except that the blue will extend only to a point about 25 degrees inside the form. The red, which is next in turn, will extend to within 10 degrees of the blue, and the green will ex-

tend to within 10 degrees of the red.

In the abnormal field there is a marked decrease in the size of the form as well as the color. The fields are irregular in shape also, but the most decided change is that of the position of the colors. Instead of being from without in, the colors are interlaced or they may even be inverted. It may so happen that the colors extend outside of the form limits.

In the study at this hospital a series of

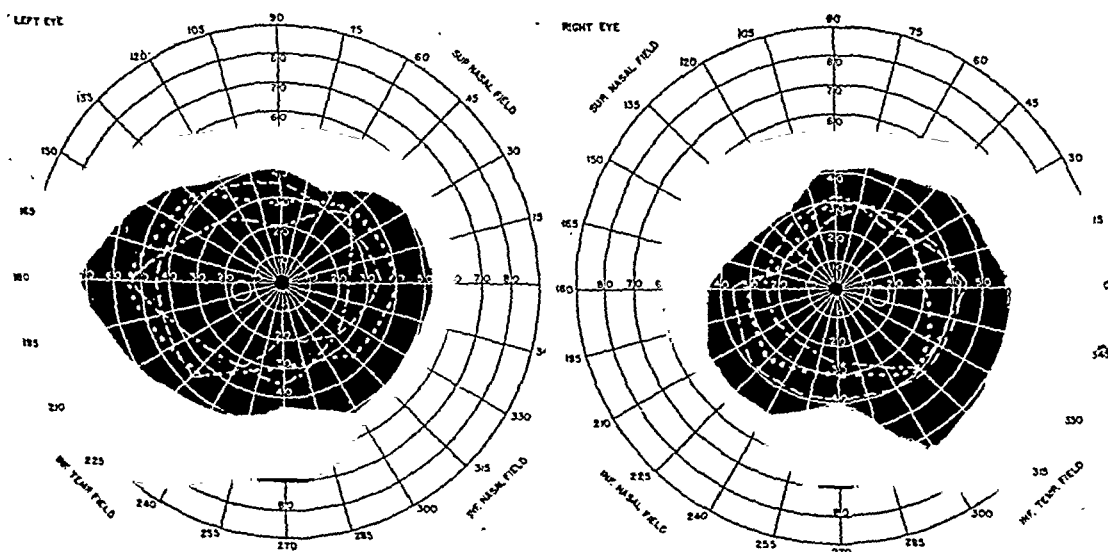

Fig. 3 (Reeder). Psychogenic field, moderate.

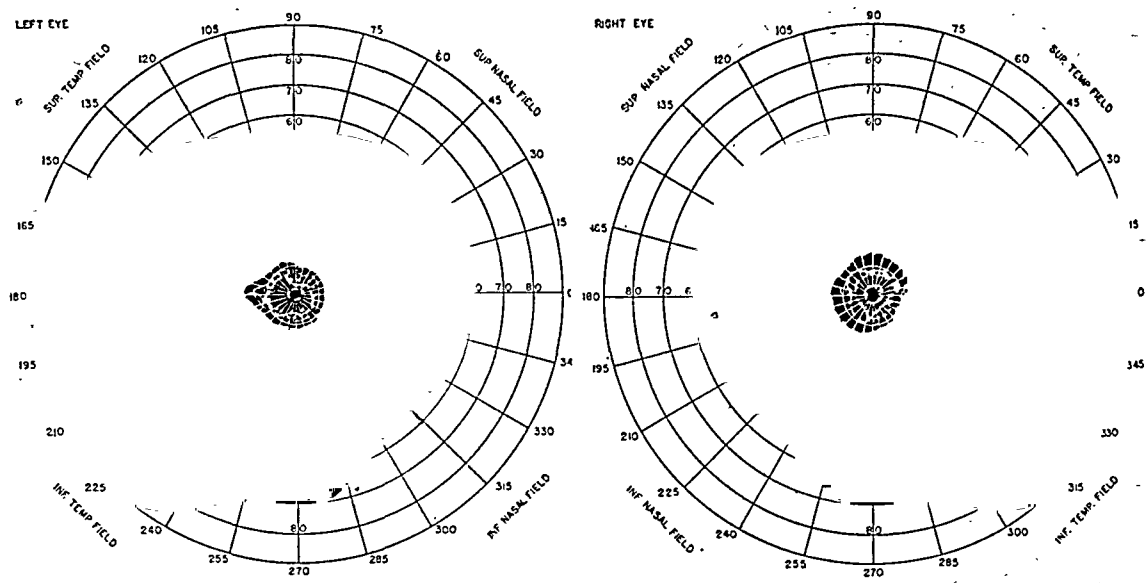

Fig. 4 (Reeder). Psychogenic field, severe. Green is the very small innermost field.

cases was chosen in which there was no evidence of pathology or only a visual error that could be corrected to normal. These cases came from all departments, and had all types of complaints. However, at no time was there any definite change that was pathologic. No other criterion than the one mentioned was used in the selection of the cases. The majority of the patients came from the Neuropsychiatry Service. Twenty-seven were seen in the Eye Department and an additional 19 were sent in by others. All of those from the Neuropsychiatric Service were psychoneurotics who complained of some type of eye symptom from pain to poor vision. It was ruled out that there was any

pathology before the fields were taken. Not all of the cases were as well defined as some, but they all showed some change that was functional. Of the 87 patients examined, 64 exhibited the psychogenic field, which ranged from mild to severe. This is evidenced in figures 2 to 4. Many of the patients presented bizarre symptoms that could not be substantiated by organic pathology. On the other hand, there were those who showed no definite pattern from the psychiatrist's point of view, and the only change that could be demonstrated was that of the functional oberration in the color fields. An illustration of the bizarre symptoms

TABLE 1
SHOWING THE DISPOSITION OF THE CASES

Source	Number	Mild	Moderate	Severe	Normal	Percent	Disposition	Duty	Cdd
Eye Dept.	27	1	6	11	8	30.2	8	19	
Neuro-Psychiatric Service	41	5	11	23	2	47.6	0	41	
Others	19	1	6	10	2	22.9	7	12

Percent	100	8.1	26.7	51.1	13.9	100			

was found in a man who came in with the complaint of constant priapism. No organic cause for this was found. Examination of the other systems of the body was made but no pathologic basis was found. Examination in the Eye Department revealed no abnormalities of the visual apparatus, and on questioning the patient unexplainable discrepancies were found in his story. A form and color field were outlined, and a functional change was found. The psychiatrist then examined the patient, and after four or five conferences was able to establish a functional diagnosis. It was believed that the fields in this case were a definite help in giving a lead in a case that was obscure from a psychoneurotic standpoint. The obscurity is due to the fact that some of the patients who come in are unwilling to talk, and the psychiatrist is unable to get a lead. Fields in a case such as this help to give the psychiatrist a point of departure in making his examination.

The table is self-explanatory in that it

shows where the cases originated, and their ultimate disposition.

CONCLUSION

It has been demonstrated that the psychogenic color field is of definite aid in the establishment of a psychoneurotic diagnosis. It is tangible evidence in an otherwise abstract diagnosis. It is a test that cannot be faked, therefore malingerers cannot make use of it. As in all things medical no claim is made that this test is infallible, but when the test is positive it is an aid to diagnosis. In this series all of the psychoneurotic patients did have the change in the color fields, from mild to severe. Eighty-seven cases were reviewed; 72 were separated from the service for psychogenic reasons; 19 of the 72 were discovered by their psychogenic type of color field before they had had any association with the neuro-psychiatrist.

Hammond General Hospital.

TUMOR OF THE LACRIMAL GLAND*

JOHN J. FLICK, M.D.
Indianapolis, Indiana

The lacrimal gland is rarely the site of pathologic processes. The reasons for this are its small size, excellent blood supply, dependent drainage, and protection from traumatic influences. Pathologic swellings of this organ may be considered in four groups: 1. Inflammatory processes. Infection may be an acute suppurative one or one of the forms of bilateral chronic granulomatous hyperplasia, commonly syphilitic or tuberculous. 2. Neoplasms. 3. Cysts or dacryops. These may result from retention of secretion due to obstruction of the lacrimal ducts. 4. Mikulicz's disease. Various forms of this unique syndrome occur in blood dyscrasias particularly leukemia. It also occurs physiologically in weeping and menstruation.¹

Tumor of the lacrimal gland is usually of the mixed type.² Ziporkes³ stated that "The salivary and lacrimal glands are the seat of mixed tumor and are probably derived from the buccal ectoderm, with possible admixture from the maxillary periosteum or the branchial cartilage. They represent elements in the form of strands of cells, alveoli, diffuse masses of mesoblastic tissue, chiefly cartilaginous, mucous and cellular connective tissue. Any of these may predominate, giving rise to nearly pure chondroma, sarcoma, or carcinoma, but usually all the types of cells are represented." Mixed tumors occur in various forms from highly differentiated types to infiltrative anaplastic carcinoma. They are to be regarded always as potentially malignant. As a rule they are well encapsulated and grossly

firm. When invasive they tend to erode into the cranial cavity through the roof of the orbit. They rarely metastasize but are very prone to recur locally after removal.¹

SIGNS AND SYMPTOMS

The first and most constant symptom is proptosis of gradual onset. The eyeball is displaced downward, nasalward, and forward from the socket. Diplopia is exceedingly annoying. The displacement of the images is vertical and is increased when the patient looks toward the side of the lesion. In a few cases the proptosis is extreme. In the case herein reported the eye had repeatedly extruded between the lids, which would fall behind it. This caused such excruciating pain that manual replacement of the lids had to be done under general anesthesia. Vision in the affected eye may be compromised because of traction upon the optic nerve as the eye is slowly and gradually luxated. This diminution in visual acuity may disappear or become much less marked after successful removal of the tumor.⁴ Pressure on the posterior portion of the eyeball may indent it, producing the ophthalmoscopic picture of detachment of the choroid.³ The cornea may be exposed and develop exposure keratitis. The visual field may be normal or show a small central scotoma for form and color.⁴ A firm mass is usually palpable in the region of the superior lateral orbital margin under deep pressure of the finger.

DIFFERENTIAL DIAGNOSIS

Proper classification of these cases compels a consideration of all the causes

*From the Indiana University Hospitals.

of exophthalmos. Dermoid cyst may be primary in the upper lid and should be considered in all cases in which the proptosis is slight and enlargement of the upper lid is marked. An aneurysm often pulsates, and a bruit may be heard over it. Retro-orbital hemorrhage and abscess are to be considered. One should remember luetic periostitis of the orbit, also soft, fluctuant mucocele extending from the anterior ethmoid or frontal sinus. The rare glioma of the optic nerve is to be seriously considered if there is complete blindness with dilated pupil and marked nerve-head pallor. In cases in which the ocular fundus cannot be seen, the possibility of a retrobulbar extension of a primary intraocular malignancy must be borne in mind. Measures should be taken to rule out systemic conditions producing exophthalmos, particularly Hand-Schüller-Christian's disease and Graves's disease. Careful neurologic examination should be conducted in all cases. Radiologic studies are exceedingly important in the diagnosis, prognosis, and intelligent selection of the route of surgical approach. Roughening, distortion, or asymmetry of the sphenoidal ridges leads to suspicion of orbital extension of an intracranial growth or *vice versa*. Enlargement of the optic foramen usually indicates tumor of the optic nerve. Concentric expansion of the orbital walls betokens a large tumor requiring wide exposure. Radiologic evaluation of paranasal-sinus disease requires the attention of a competent radiologist. Some orbital tumors exhibit calcification, particularly hemangioma and Koch's infections.

TREATMENT

The treatment is surgical. Irradiation may be considered an adjunct only. Surgical approach to the lacrimal gland is made by one of three routes. The first of these

is the direct approach through the skin of the upper lid or the conjunctiva of the superior cul-de-sac. This is satisfactory for small tumors but gives poor exposure; where the palpebral portion of the gland shows marked enlargement this may be the method of choice. The second approach is the Krönlein operation which gives excellent exposure by resection of the lateral wall of the orbit as a bone flap. This approach is peculiarly adaptable to lacrimal tumors which are usually laterally situated in the orbit. It gives access to growths above or within the muscle cone. The third method is the cranial approach. This is the most radical but has much in its favor. In cases in which the growth is large, the diagnosis uncertain, under conditions in which it seems highly desirable to save the eye, this method in good hands is excellent. It should always be used, of course, if neurologic signs of brain involvement are present. Because of the pronounced tendency of these tumors to erode the bony roof of the orbit, the removal of this involved bone cannot but decrease the number of recurrences from this cause. It is important to remember, however, that should it seem necessary at any time to exenterate the orbit, such an operation is difficult to perform from above at the time of the craniotomy and hazardous to perform at a later date from below because of the possibility of meningeal infection. It is axiomatic in the treatment of these tumors that it is important to save the eyeball only if all the tumor can be removed.^{3, 5}

Most of the cases in the literature have been operated on by the direct approach or the Krönlein approach. Chief among those who champion the cranial approach is Dandy,⁶ who believes that all orbital growths should be attacked in his manner. It is his opinion that from 75 to

80 percent of all orbital tumors are also intracranial, that less radical procedures lead to incomplete removal of the tumor. It is needless to say that in cases in which there are obvious malignancy and total blindness with degenerative changes in the globe, total or subtotal exenteration of the orbit is the procedure of choice.

CASE REPORT

A white man, aged 45 years, was first seen in the out-patient Eye Clinic on

outer angle of the left orbit and it was thought that the left lacrimal gland was either displaced or enlarged. No crepitus could be detected in the periorbital soft tissues after forcible blowing of the nose. The Zeiss exophthalmometer read 14 mm. for the right eye and 32 mm. for the left. The left upper nasal cavity was almost completely obstructed.

Blood counts and urinalyses were normal. Blood serum cholesterol was 450 and total lipids 1,032. The Kline and

Fig. 1 (Flick). Preoperative photograph showing vertical and axial displacement of the left globe.

August 18, 1941, complaining of a bulging left eyeball. There was a history of a gradually progressing exophthalmos of the left eye for eight years. The patient stated that he had been struck over the left eye with a shovel. There had been several attacks in which the eye had proptosed completely from the socket to be returned manually under anesthesia.

Corrected vision of the right eye was 20/13 and of the left 20/50. There was vertical diplopia increasing on levoversion, indicating relative elevator insufficiency of the left superior-rectus muscle. The left eyeball appeared to be displaced downward. The peripheral field of the left eye was normal with a 5/330 white stimulus, and the fundus examination of both eyes was essentially negative.

A tumor mass was felt at the upper

Mazzini tests upon the blood were negative. Neurologic examination revealed no signs of central-nervous-system involvement.

X-ray examination (fig. 2) revealed an increased density of the intraorbital contents on the left side, giving rise to a clouded appearance of the orbital shadow. There was some slight osteocondensation of the anterior nasal rim of the left orbit. The lacrimal fossa of the left orbit was seen to be enlarged to approximately twice the size of that of the right. There was definite thinning of the floor of the left lacrimal fossa produced by erosion, and the supero-lateral limits of the orbital wall in this region were irregular and partially destroyed. There seemed to be an area of bone destruction extending from the lacrimal fossa on the left side into the floor of the anterior

cranial fossa. The optic foramina were equal and normal in size and shape on the two sides.

On October 23, 1941, a small osteoplastic flap was reflected over the left frontal lobe by Dr. Robert L. Glass. The anterior limb of the flap lay just above the frontal sinus. The dura was elevated from the roof of the left orbit. The roof

detritus was evacuated under pressure. Increased intraorbital pressure had caused erosion of the bony wall of the ethmoid cells, establishing free communication between these cells and the orbit. Examination of a frozen section was reported "probable malignant neoplasm." Complete removal of the growth appeared to be inadvisable. About three-fourths of

Fig. 2 (Flick). Roentgenograms of the orbits showing the equal and normal optic canals. Arrows indicate bony erosion and destruction in the region of the left lacrimal fossa.

of the orbit was paper thin. Bony erosion was noted in the antero-lateral surface of the orbit, and a small amount of friable tumor was eroding through the bone in this region. The roof of the orbit was partially removed by the use of a rongeur. A large tumor was found in the orbit behind the globe. The tumor lay mostly in the lateral and superior divisions of the orbit and had displaced the eyeball forward and the cone of muscles medially. The tumor appeared to have a thin capsule. It was soft and friable and somewhat grayish in color. On its medial surface was a large cyst. The cyst was incised and a thin fluid containing much

it was removed. The pathologic report of Dr. Frank Forry is as follows:

The section for study is stained with hematoxylin and eosin. It shows numerous small, discrete masses of tumor tissue. These present a varied tissue pattern. In some areas tumor cells form alveolar masses outlined by a very delicate connective-tissue stroma (fig. 2, A).

In some other areas the tumor cells appear as cuboidal cells, lining spaces and thus form an adenomatous pattern. These glandlike structures are evenly spaced and are usually rather widely separated by masses of closely packed tumor cells (fig. 3, A).

In other areas the tumor cells lie in thick rings and masses separated by loose stroma (fig. 3, C). In still others the tumor cells form a loose, fine-meshed reticulum within which lie round, solid masses of cells. The center of such

Fig. 3 (Flick). Photomicrograph showing the various tissue patterns found in different areas of the neoplasm.

Fig. 4 (Flick). Postoperative photograph taken on the nineteenth postoperative day showing disappearance of proptosis.

masses tends to become hyaline and laminated. Spinous processes could not be demonstrated in any of these cells (fig. 3, B).

The tumor tissue is well vascularized and in some instances the tumor cells seem to form the blood channels. In most instances, however, there is a well-defined vessel wall surrounded by a zone of loose connective tissue; this, in turn, is sharply delimited by surrounding tumor tissue.

The tumor cells are epithelial in type and show a remarkable pleomorphism. They appear as round, oval, spindle, cuboidal, and stellate cells. The nuclei are round or oval. The nuclear membrane is sharply outlined. The chromatin is

Diagnosis: Neoplasm showing the features of adenocarcinoma.

The postoperative course was uneventful. The proptosis and diplopia both disappeared soon after the operation, much to the joy of the patient (fig. 4). He was advised to have a complete exenteration of the left orbit but refused. He was also advised to return for a series of deep X-ray treatments. This he did not do but he returned to the Eye Clinic for a check-up examination and photograph

Fig. 5 (Flick). The patient 18 months after surgery. Note the exaggerated orbito-palpebral sulcus on the left.

present as one or two coarse granules surrounded by fine dust, giving the nucleus a pale blue color. A moderate number of cells show karyokinesis. A pink-staining substance resembling ground substance, present in small amounts, occurs, with the delicate connective tissue stroma supporting the tumor parenchyma.

There are no cartilaginous cells, and lymphoid tissue is not present in this section.

April 28, 1943, at our request (fig. 5). At this time the visual acuity in each eye was 20/15 corrected. The exophthalmometer read 17 for the right eye and 21 for the left. There was a distinct hollow in the left eyelid over the region of the lacrimal gland (see illustration). The pa-

tient made no complaint at this time.

CONCLUSIONS

1. Tumor of the lacrimal gland is a clinical as well as a pathologic entity.

2. Preoperative diagnosis is possible in a high percentage of cases.

3. The treatment is surgical.

4. A case of tumor of the lacrimal gland is reported.

A REPORT ON DEFECTS FOUND IN TONOMETERS EXAMINED AT THE CHECKING STATION OF THE NATIONAL SOCIETY FOR THE PREVENTION OF BLINDNESS

MARK J. SCHOENBERG, M.D.

New York

AND

ADOLPH POSNER, LT. (MC), A.U.S.

For several decades the ophthalmologic profession has regarded the Schiötz tonometer as a very useful instrument and necessary to our practice. However, more recently, ophthalmologists have come to realize that the tonometer is not so reliable an instrument as one would wish it to be.

Not only do different tonometers register varying tensions for the same eye, but successive measurements made with the same instrument may vary by as much as 3 to 4 or even more millimeters of mercury* in either direction, even though the technique is faultless. Consequently, a situation exists in which instruments used for measuring purposes do not measure but confuse; and when one considers

that many ophthalmologists are prone to base their diagnosis of glaucoma mainly on the tonometric readings, the situation becomes quite serious. Errors of technique play an important part in causing inaccurate measurements; equally responsible for unreliability are defects in construction and performance of the tonometer.

The present report on defects discovered from the examination of 68 tonometers of the Schiötz type† supports the statements made in the introductory remarks of this paper. [Since writing this report we have examined 62 more tonometers.]

The specifications for the various con-

* Slight reduction of tension with successive applications of the tonometer might be ascribed to the massage effect, as pointed out by one of us (Schoenberg. Clinical and experimental research on intraocular drainage. Arch. of Ophth. 1913, v. 42, no. 2.). However, this lowering of tension takes place only after the tonometer has been applied continuously for 10 or more seconds (usually 20" to 30").

† Only tonometers of the Schiötz type were examined because of our familiarity with the specifications for and methods of examining instruments of this type.

stituent parts of the tonometer and for the instrument as a whole, as established originally by Professor Schiötz, were adopted as the standard for the instruments submitted for examination. In the course of time, it was found that several

fects are classified as major and minor.

The major defects are those which concern those parts or units that are essential for the accuracy of performance, and each of these is a source of considerable error. The summation of two or more

Fig. 1 (Schoenberg and Posner). Major and minor defects discovered in tonometers at the checking station* of the National Society for Prevention of Blindness.

MAJOR DEFECTS

Weight of plunger, load, lever (hammer and pointer)—too heavy or too light.

Weight of tonometer—too heavy or too light.

Lever ratio— ab to bp —greater than or less than 1 to 20.

Fulcrum—wobble or looseness.
Handle—too soft.

Foot plate and foot of plunger—edges sharp or chipped.

Foot or plunger—under surface flat or convex.

Curvature of the upper surface of the testing block.

Testing block

MINOR DEFECTS

Scale markings—inaccurate; not sharp; no color contrast.

Pointer—out of shape; too far from scale; not equidistant from all points of the scale, too deep, too thick.

Plunger tip—too sharp or too flat.

Plunger in cylinder—presence of friction—too loose or too tight.

Groove of plunger and upper extremity of interior of cylinder—contains foreign matter and sticks.

Foot plate—radius of curvature too large or too small.
Foot plate—diameter—too large or too small.

* Under the direction of Mark J. Schoenberg, M.D., and Adolph Posner, M.D.

more specifications and methods had to be added to those used by Schiötz at the Oslo checking station. Thus, at our own station each instrument received was submitted to an examination consisting of 21 separate steps (table 1).

For brevity's sake the data obtained are summarized in figure 1 and table 1. Figure 1 indicates the various places in tonometers where defects in construction and performance were found. The de-

fects may render the instrument utterly unreliable.

The minor defects affect the accuracy of tonometers to a lesser degree, but the summation of several minor defects may constitute a major one.

Major defects. 1. The weight of the plunger load lever (hammer and pointer) unit should be 5.5 grams. An increase of one gram causes a reading toward a lower tension of one division or more on

the scale. This error is all the more considerable if the tension in a particular case happens to be in the critical zone* of the tonometric curve.

2. If the weight of the entire tonometer exceeds the specification of 16.5 gm. by several grams, it will be the source of a serious error in measurement.

3. The lever ratio, the ratio between the length of the short arm ab (4 mm.) and that of the long arm bP (80 mm.) should be 1:20. The upper extremity of the pointer (P) moves to the right 20 mm. (from 0 to 20). Thus, for each pointer deflection of one division on the scale (there are 20 divisions), the plunger makes a depression in the cornea of 0.05 of one millimeter. Any minute deviation from the ratio of 1:20 may be a source of a considerable error in the registration of the tension.

4. If the point of rotation of the lever (the joint between hammer and pointer) at the fulcrum is not stable (loose) or if the lever itself does not fit properly at that point on the fulcrum, a wobble develops during the excursion of the pointer along the tonometer scale. The pointer will then not always stop precisely at the same line, when the tonometer is applied several times in succession to the same eye, but will perform an oblique torsional movement causing a reading error of one or more divisions. This is frequently the cause of inconsistent registration on the scale.

5. If the handle is too soft, it may be pressed against the frame when placed on the eye. Hence, this pressure on the eyeball will register artificial hypertension.

6. If the radius of curvature of the testing block is greater or less than 16 mm., it does not match the curvature of the footplate, and the advantage of check-

ing the tonometer for the zero point is lost.

7. If the edges and under surfaces of the foot plate and foot of plunger are rough, sharp, or chipped, a corneal abrasion may follow the application of the tonometer.

8. A convex undersurface of the foot of the plunger will cause an error (reading toward lower tension) by several divisions on the scale; a flat undersurface of the plunger will cause an error (toward lower tension) of about one division on the scale.

Minor defects. 1. If the scale markings are not sharp, or do not contrast adequately with the white background of the scale plate, one may experience some difficulty in reading them.

2. If the upper extremity of the pointer is too far in front of the scale, an error in reading will result due to the parallax displacement; if the pointer is too close to the scale it may scrape against it; if too broad it will cover the dividing lines or the space between them and will interfere with correct reading.

3. If the tip of the plunger is too sharp or too flat, it is liable to produce either a deep depression or a long groove on the undersurface of the hammer, and friction will result.

4. If the diameter of the plunger is too large or too small, it will fit either too snugly or too loosely in the cylinder, respectively, and cause friction. In either case an error in registering the tension will occur.

5. If the interior of the cylinder and the surface of the plunger lack smoothness or are sticky from the presence of foreign matter the friction is increased beyond the tolerance point.

6. If too large or too small, the radius

* The critical zone on the tonometer scale is that portion which registers the borderline between "normal" and "high." Obviously, to the clinician, this is the most important part of the scale.

TABLE 1

REPORT ON 68 TONOMETERS EXAMINED AT THE CHECKING STATION* OF THE
NATIONAL SOCIETY FOR THE PREVENTION OF BLINDNESS

Items Checked	Specifications, Standard with Tolerances	No. of Tonom- eters within Standard	Defective Tonometers					Total Tonom- eters Checked ^a
			Greater than	No.	Less than	No.	Total no.	
1. Weight of tonometer	16.5 gr. \pm .5	45	17. gr.	7	16. gr.	12	19	64
2. Weight of plunger plus hammer, pointer, and load	5.5 gr. \pm .25	13	5.75 gr.	48	5.25 gr.	4	52	65
3. Weight of load 7.5	2. gr. \pm .05	45	2.05 gr.	8	1.95 gr.	10	18	63
4. Weight of load 10	4.5 gr. \pm .05	44	4.55 gr.	6	4.45 gr.	14	20	64
5. Diameter of foot plate	10.1 mm. \pm .1	17	10.2 mm.	12	10. mm.	38	50	67
6. Diameter of plunger	3. mm. \pm .05	47	3.05 mm.	5	2.95 mm.	15	20	67
7. Radius of curvature of foot plate	15. mm. \pm .5	49	15.5 mm.	7	14.5 mm.	11	18	67
8. Radius of curvature of testing block	16. mm. \pm 0	13	16. mm.	12	16. mm.	41	53	66
9. Reading on 15 mm. disc	-1. mm. \pm 0	17	-1. mm.	37	-1. mm.	13	50	67
10. Reading on 16 mm. block	0 \pm 0	10	0	43	0	14	57	67
11. Reading on own block	0 \pm 0	53	0	5	0	8	13	66
12. Lever ratio	1 to 20 \pm 0	26	1 to 20 ^b	29	1 to 20 ^c	12	41	67
13. Radius of curvature of foot of plunger	concave	53	flat	11	convex	3	14	67

^a Impossible to check all items on total of 68 tonometers because of missing weights and test blocks in the set, of handles, and instruments out of alignment.

^b Higher ratio indicates reading is too soft.

^c Lower ratio indicates reading is too hard.

Additional items recently added to the procedure of checking:

14. Condition of division lines on scale (blurred, too thick)

15. Distance of pointer from scale (too far, too close)

16. Shape of pointer (bent, too broad or thick)

17. Presence of friction between plunger and cylinder

18. Condition of lever (wobble)

19. Condition of plunger (loose, edge chipped or sharp)

20. Condition of foot plate (edge chipped or sharp)

21. Condition of groove of plunger and interior of cylinder (presence of foreign matter)

* Under the direction of Adolph Posner, M.D., and Mark J. Schoenberg, M.D.

These specifications have been adopted by the Committee on Standardization (Dr. Jonas Friedenwald, chairman) with some slight modification. A paper on the subject will be published in the near future.

of curvature of the foot plate will impair the correct adjustment on the testing block.

7. The diameter of the foot plate, if too large or too small, will cause inaccurate reading because it changes the weight resting on the unit area of the cornea.

Remarks. The first two columns in this table present the lists of the items to be checked in tonometers and the standard Schiötz specification for each item. The remaining columns give the number of tonometers in which each of the specifications was found to be correct or defective.

The discovery of the same defects in a large percentage of the tonometers ex-

amined to date leads us to believe that these instruments are fairly representative of the general run of defective tonometers. These instruments were sent to the New York checking station by ophthalmologists in 17 different states* and Canada.

A glance at the table reveals the following figures regarding a few of the major defects found in the group of tonometers examined:

1. The weight of plunger, load, and lever is either too high or too low in 52 out of 65 tonometers (80 percent).

2. The weight of the entire tonometer is not according to standard in 19 out of 64 (29 percent).

3. The radius of curvature of the test-

* The following is the list of the states from which tonometers were sent to the New York checking station: California, Connecticut, Georgia, Illinois, Indiana, Kentucky, Louisiana, Massachusetts, Michigan, Minnesota, Nebraska, New York, North Carolina, Ohio, Oklahoma, Pennsylvania, Utah.

ing block is not according to the standard in 53 out of 66 (80 percent).

4. The lever ratio is defective in 41 out of 67 (61 percent).

CONCLUSIONS

The following conclusions seem incapable:

1. A large percentage of tonometers (Schiötz type[†]) contains defects of construction and of performance. These defects point to one of the two reasons for the unreliability of many tonometers.[‡]

2. Every tonometer already in use should be checked at a reliable checking station at the earliest possible time.

3. Inaccurate tonometers should not

be used until the important defects are corrected or adjusted.

4. It is urgent that a number of reliable checking stations be established under the direction of ophthalmologists in appropriate locations, throughout this country.

5. It is important that precision mechanics be found who are able to put defective tonometers in good working order.

6. Manufacturers of tonometers should be urged to have their instruments checked and certified at reliable checking stations before placing them on the market.

667 Madison Avenue.

[†] No one knows how many of the other types are defective.

[‡] The other reason is defective technique of tonometry.

OPTIC-NERVE ATROPHY IN MALIGNANT NASOPHARYNGEAL TUMORS

MARTHA RUBIN FOLK, M.D.
Chicago

Malignant nasopharyngeal tumors are of interest to the ophthalmologist because of the involvement of the ocular nerves. Involvement of the optic nerve is of special interest because of its infrequent occurrence.

The pathologic study made on the second of the two cases here reported has clarified and opened the way to a better understanding of the first case, which has not come to autopsy.

CASE REPORTS

Case 1. T. R., 30 years old, a white housewife, was referred to the Eye Clinic of the University of Illinois Research Hospital by the Ear, Nose, and Throat Clinic on July 23, 1941, because of a paresis of the right external-rectus muscle and right optic-nerve atrophy. She stated that about a year before she had consulted a physician because of a sore throat and sinus infection; she also complained then of a headache on the right side which began at the bridge of the nose and radiated to the right temporal region. A few months later she developed a diplopia.

The Ear, Nose and Throat Department's report was as follows: "The septum was pushed to the left, showing a pinkish tumor in the epipharynx with an irregular surface resembling adenoids. Hearing was diminished on the right side. X-ray study showed an increased density over the sphenoid sinus (fig. 1), and the sellar outlines were blurred. A biopsy specimen from the epipharyngeal tumor, removed on August 1, 1941, revealed a transitional-cell carcinoma.

The Wassermann test was negative.

Blood count: Red blood corpuscles 3,500,000; white blood corpuscles 6,500; hemoglobin 65 percent. The neurologic examination on August 9, 1941, showed a paresis of the right sixth nerve and hypalgesia of the right side of the face.

Examination of the eyes on August 12, 1941, showed vision R.E. was 5/200;

Fig. 1 (Folk). X-ray study of case 1. Sph., sphenoid cloudy due to tumor invasion. Note the absence of tumor within the epipharynx. R, roof of the orbit; S, sella turcica; B.Sph., body of sphenoid; V, vertebrae; Mand., mandible; A.Sph., anterior wall of sphenoid.

Fig. 2 (Folk). Case 2. F.C., falx cerebri calcified; C.G., crista galli; E, ethmoid; S, nasal septum; D.N., diastasis between the two alveolar processes of maxilla.

L.E. 20/20. There was a slight ptosis of the right lid. Some esotropia for distance and esophoria for near was present. There was a weakness of the right external-rectus muscle. The candle-light test showed a homonymous diplopia which increased when the eyes turned to the right. The irides were brown. The pupil of the right eye did not react to direct light but did react consensually. The pupil of the left eye reacted normally. The disc of the right eye was pale, its margins were clearly outlined, and the blood vessels slightly narrowed. The rest of the fundus was normal. The visual field of this eye showed a concentric contraction of 20 degrees and a complete loss of red and green fields. The intraocular pressure was normal.

Patient was given 10,000 r in 40 sessions. Under this treatment the growth disappeared from the nasopharynx. The eyes became parallel and there was some improvement of vision in the right eye from 5/200 to 20/200. However, the neuralgia of the right side, the headache, and the wasting of the body continued.

Case 2. C. P., five years old, a white girl, had been a full-term baby, well except for measles in April, 1940, and occasional colds. In December, 1941, she developed a stuffiness of the nose. A physician was consulted, and he found a growth in the nose which he considered to be nasal polyps. He tried to remove them by applying trichloroacetic acid. The child immediately lost consciousness for

Fig. 3 (Folk). Case 2. D, enlarged diploic veins; S, sella turcica; T, tumor; A.Sph., anterior wall of sphenoid; R, roof of orbit; Mand., mandible.

45 minutes. That evening the girl's right cheek and upper lid began to swell and her eyes to water. Shortly after this she began to complain of dimness of vision. According to the history reported by the parents, the swelling of the lids receded but the vision became progressively worse. The child grew exceedingly apprehensive and irritable. She began to have

great difficulty in breathing. Because of the apparently complete obstruction of the nose a rhinologist decided to remove the growth, but immediately after receiving the anesthetic the child stopped breathing and was revived with difficulty. No surgery was performed. About three days after this the right lid began to droop, both eyes teared and began to

Fig. 4 (Folk). Case 2. F.S., frontal sinus; S, nasal septum; M.S., maxillary sinus; H.P., hard palate; Note the cloudy structure in the area of the posterior ethmoid and sphenoid due to invasion of tumor.

bulge. Her vision decreased to the point where the child could not recognize her parents, and her fearfulness increased.

On admission to the Pediatric Department of the University of Illinois on March 9, 1942, the child was extremely apprehensive and kept her eyes closed as if she had photophobia. In the nose, a tumor extended into the epipharynx and pushed the nasal septum to the right side. X-ray studies showed an increased density over both maxillary sinuses and some of the left ethmoid cells (figs. 2 and 4). There was a complete absence of intranasal bony structure. The blood chan-

nels over the anterior part of her skull were unusually prominent and the intermaxillary suture was open (fig. 3).

The eye findings on March 10th revealed a moderate proptosis of the right eye and slight proptosis of the left eye. Vision could not be taken because of poor coöperation. There was a mild suppurative dacryocystitis on the right side. The pupils were 6 mm. in diameter and reacted poorly to light, but the eyegrounds appeared normal.

On March 17th, the proptosis on the left side was marked. Both pupils were dilated to 6 mm. and neither reacted to

Fig. 5 (Folk). Case 2. Frontal section through the sphenoid field within tumor masses. T, tumor; II, optic nerve; F, superior orbital fissure; B, newly formed bone; S, small wing of sphenoid; D, dura; a, indicates an erosion of the small wing of sphenoid.

light. There were a complete external ophthalmoplegia, and a ptosis on the right side; the palpebral fissure was narrowed to a slit and apparently there was complete blindness. Wassermann and Kahn tests were negative.

On March 25th the child died.

The autopsy revealed a proptosis of both eyes. The nasal septum was deviated to the right. The calvarium was thin and on its inner aspect near the vertex there were two rounded-out depressions. The dura was elevated uniformly throughout the region of the cribriform plate, the planum sphenoidale, and the region of the sella turcica. The dura was not perforated. All of the paranasal sinuses were obliterated by a white, boggy tumor mass which had destroyed the bone and cartilage but was limited by the mucous

membrane lining the sinuses. The lacrimal bone on the right side was partially preserved (fig. 3).

MICROSCOPIC EXAMINATION

Palate: The tumor was extremely cellular, containing for the most part spindle cells. It was separated from the glandular layer on the oral surface of the soft palate. The bone of the hard palate was separated from the tumor but showed marked osteosclerosis and less-marked osteogenesis due to pressure of the new growth.

Hypophysis: The largest part of the section consisted of a tumor mass which replaced the entire body of the sphenoid and reached the dura in the region of the anterior clinoid process but did not perforate the dura at any place. In the

region of the posterior clinoid process the tumor was distinctly separated from the very active red marrow of the clinoid process. The synchondrosis sphenooccipitalis was reduced to a very narrow layer of cartilage which was eroded but not perforated by the tumor. The hypophysis was pressed against the posterior clinoid process. The new growth

consisted of atrophic trabecula which were lying fairly parallel and extended toward the internal layer of the dura in a right or acute angle. There was loose connective tissue between these trabecula but the connective tissues did not present infiltration. In other places the tumor perforated the outer layer of the dura and the newly formed bone reached the inner

Fig. 6 (Folk). Case 2. Weigert stain of optic nerve.

consisted of pleomorphic cells and many giant cells. Spindle cells were also seen but in fewer numbers. The diagnosis of the tumor was *spindle-cell sarcoma*.

Optic nerve: The tumor contained parts of the intersphenoidal synchondrosis and remnants of the mucous membrane of the sphenoid. Toward the dura the tumor was covered with various tissues. In the area of the planum sphenoidale the dura was markedly thickened and between the layers of the dura a layer of new bone was formed (fig. 5). The new bone con-

sisted of atrophic trabecula which were lying fairly parallel and extended toward the internal layer of the dura in a right or acute angle. There was loose connective tissue between these trabecula but the connective tissues did not present infiltration. In other places the tumor perforated the outer layer of the dura and the newly formed bone reached the inner

sheath of the dura, which was not perforated at any place. Laterally, the tumor surrounded the optic nerves but in no place did it perforate the dural sheath (fig. 6). The ophthalmic arteries on both sides were normal. While the tumor did not perforate the periosteum, it apparently pressed the optic nerve toward the lesser wing of the sphenoid which separated the optic canal from the superior orbital fissure, the lesser wing of the sphenoid being thereby destroyed in that area of

pressure. The tumor advanced toward the superior orbital fissure but did not penetrate the periosteum of the orbit.

COMMENT

In case 1, the typical clinical picture of a carcinoma of the epipharynx was presented. Inasmuch as the symptoma-

sphenoid toward the optic canal and involve the opticus in that way.

In case 2 it is shown that the optic nerve might be involved in another manner. Here a very malignant sarcoma invaded both sphenoid sinuses and after destroying the lateral wall of these sinuses penetrated the optic canal so that the

tology and pathology of these cases are very well known, an exhaustive discussion of the laryngologic and neurologic background of the cases is omitted. Attention is called, however, to the optic atrophy in the case, for a study of the literature proves that optic atrophy is not frequently encountered in cases of malignancies of the epipharynx.

The figures in table 1 are only approximations. This is due to the fact that (1) not all cases were observed for a sufficient length of time for them to acquire symptoms of disease of the optic nerve and other eye-muscle nerves which appear in the late stages of the disease, and (2) only certain types of tumors have a tendency to destroy bones and involve the ocular nerves.

The question arises as to how the involvement of the optic nerve can be explained in cases of epipharyngeal malignancies. Several years ago Jacob⁶ pointed out that epipharyngeal tumors may grow along the eustachian tube into the skull and advance along the great wing of the

optic nerve was almost completely surrounded by tumor tissue. The tumor then advanced toward the superior orbital fissure. It is interesting to note that the periosteum of the orbit was not perforated by the tumor so that neither the contents of the orbit nor the contents of the superior orbital fissure were infiltrated by tumor tissue. The periosteum of the orbit was pushed forward, inducing the proptosis observed in this case.

Most interesting are the findings concerning the optic nerve. As already mentioned, it was almost entirely surrounded by tumor tissue. Only the roof of the optic canal, which belongs to the anterior fossa of the skull, was still present, although pathologically changed. It should be pointed out that neither the dural sheath of the optic nerve nor the dura of the anterior cranial fossa was perforated at any place; hence there was no sarcomatous infiltration within the optic nerve.

The microscopic findings showed that the optic nerve in this case could be

easily damaged by pressure of the tumor toward the roof of the optic canal and not by sarcomatous infiltration, if the nerve were to be impaired at all.

Whether or not the optic nerve in case 2 was functioning, cannot be definitely stated. I can only report that the nerve when stained with Weigert's solution, which stains the myelin sheath but not the axis cylinders of the nerves, presented normal myelin sheaths. However, this observation must be carefully evaluated because the child died shortly after the onset of symptoms. It is possible that in spite of what was indicated by Weigert's technique, the osmium technique of Marchi would have indicated a degeneration of the myelin sheath. Unfortunately, neither the method of Marchi nor the silver method for impregnation of the axis cylinders could be employed as the condition of the specimen did not permit it. It is, therefore, not possible to state that the optic nerve was entirely normal.

At any rate, case 2 proves that the optic nerve might be involved by perforation of the lateral wall of the sphenoid sinus by a malignant tumor within the

sphenoid sinus. As case 1 presents a definite involvement of the sphenoid sinus, proved by the X-ray picture, it is obvious that the optic atrophy in this case can be explained as due to the same conditions that obtained in case 2, as revealed by the microscopic findings.

CONCLUSIONS

1. Involvement of the optic nerve in malignant tumors of the epipharynx is not frequent.

2. The optic atrophy in the cases herein described is preceded by invasion of the epipharyngeal tumor into the sphenoid sinus. This fact explains why the appearance of the optic atrophy is late.

3. From the sphenoid sinus the malignant tumor may invade the optic nerve after perforating the lateral wall of the sphenoid sinus.

4. The dural sheath of the optic nerve as well as the periosteum of the orbit and the dura is more resistant to aggression by the tumor than is bone tissue. This holds true for sarcoma.

HYPERPYREXIA IN THE TREATMENT OF ACUTE OCULAR INFLAMMATIONS*

HARRY C. KNIGHT, M.D., MAYO EMORY, M.D., AND NEIL CALLAHAN, M.D.
New Orleans, Louisiana

The treatment of acute inflammatory diseases of the eye has resolved itself into three phases: 1. Standard ophthalmologic management, including local therapy and chemotherapy. 2. The location and elimination of infectious foci. 3. Pyretotherapy, which usually consists in giving the patient frequent injections of some pyretogenic agent, usually a foreign protein (typhoid vaccine or sterile milk). In most cases the mild febrile response obtained, usually less than 104 degrees and of short duration, is insufficient to give any material benefit in severe cases. Only a few patients are given the benefit of the intensive and prolonged therapeutic fever that is obtained with the hypertherm.

The usefulness of the more intensive pyretotherapy cannot be overestimated. It is the belief of the writers that much visual loss could be prevented, and much intense suffering rapidly alleviated, by vigorous application of this type of treatment. It is far more generally available than is commonly realized, since most clinical centers possess some type of fever cabinet employing either the Kettering or a similar principle.

A group of 51 cases of *nonsyphilitic* inflammatory diseases of the eye has been reviewed to demonstrate the striking effectiveness of this method of treatment. These were all cases of severe inflammatory diseases, the prognosis of which was grave had the treatment been confined to routine measures only. In most of these cases foreign-protein-shock therapy and thorough local therapy had previously been used without arrest of

the progress of the disease. Some of the cases were referred to the Department of Fever Therapy by the Department of Ophthalmology of this hospital, the rest were sent by prominent ophthalmologists of this city. It is recognized that many of the patients would have recovered partial vision eventually under other forms of treatment, but the rapid relief of pain and the dramatic speed of recovery with the hypertherm suggest that an appreciable percentage of vision was saved in these patients, many of whom were restored to perfect vision.

Treatments were all given in fever cabinets which use the Kettering principle of hyperpyrexia. The lower level of therapeutic fever is considered to be 104°F., and most treatments are maintained above that level for five hours. The exact level of temperature used depends upon the condition to be treated and the physical condition of the patient. Almost all patients are able to take a five-hour treatment at 105 degrees, which is the usual level for eye conditions. Gonococcal infections require a temperature of 106-107°F., with longer treatments preferred, and the concurrent use of sulfathiazole is suggested.

Treatments are given at intervals of three to five days for as long as is deemed necessary. When these treatments were first used in ocular diseases, we were happy to get relief of pain and arrest of the progress of the disease in the eye. It was felt that the matter of plastic exudates, vitreous opacities, posterior synechiae and such conditions were in the hands of the ophthalmologists. It became evident, as earlier cases were reviewed, that those patients who had more treat-

*From the United States Public Health Service.

ment had less residual damage, even though they had been apparently hopeless at the beginning. Now treatments are continued, unless the patient's physical condition prevents it, until all improvement has stopped. This is an important observation. It must not be construed as meaning that cases with old, long-standing opacities of the vitreous, old posterior synechiae, or old severe conjunctival scarring will benefit from any amount of

cases listed as having "*excellent results*" there was practically no loss of vision. In cases listed as "*satisfactory results*" there was marked symptomatic improvement but some residual visual impairment; in those listed as "*improved*" there was arrest of the progress of the disease and relief of the acute symptoms but no visual improvement. Cases listed as "*failures*" resulted in no symptomatic relief or visual improvement. In cases listed as "*re-*

fever therapy. It is only when such conditions are in process of formation and are still plastic that absorption can be obtained. The logical conclusion from this is that the more severe inflammatory conditions of the eye should be treated in the hypertherm at the very beginning of therapy. Early recognition of those cases requiring hypertherm treatment depends upon the alertness of the attending ophthalmologist and his understanding of the value of this treatment in these cases.

Table 1 lists by diagnosis the diseases treated in this series of cases, showing the results of treatment in each group. In

lapses" there was variable early improvement which did not persist.

There is a total of 37 patients in whom there were excellent and satisfactory results and whose vision has been restored to normal limits. These may be considered as cured by the treatment. The duration of the disease before the inauguration of fever therapy and the number of treatments given are the two factors which seem to govern the difference between excellent and satisfactory results. It is gratifying to realize that a large proportion of these patients would have been partially or totally blind in the absence of pyreto-

TABLE 2

DATA ON 10 CASES OF OCULAR INFLAMMATION TREATED WITH PYRETOTHERAPY

Patient	Diagnosis	Initial Vision		Signs in Eye								Pain	No. of days previous treatment	Fever Treatments			Results		Final Vision		Remarks

TABLE 3

IMPROVED: SYMPTOMATIC RELIEF, AND ARREST OF PROCESS, WITHOUT IMPROVEMENT OF VISION

Diagnosis	Prognosis at Start of Treatment	Number of Treatments Given	Response to Treatment	Remarks
Gon. ulcer of cornea	Poor	2	Relief of pain and arrest of gonorrhea	Treatment stopped because pt. noncoöperative. More treatment would have helped this case
Gon. ulcer of cornea	Hopeless	3	Relief of pain and arrest of gonorrhea	Eye was almost destroyed before treatment started. Enucleation done
Optic neuritis complication of cataract operation	Fair	4	Neuritis was checked, no visual improvement	Loss of vision was gradual but unchecked until fever therapy
Foreign body; Postop. infection of stump after enucleation	Poor	7	Relief of pain before enucleation and rapid improvement of post-op. infection	Aside from relief of pain, the most benefit was in treatment of dangerous infection of stump
Traumatic degeneration and infiltration, left eye with blindness	Hopeless, enucleation indicated	2	Some relief of pain obtained	Palliative relief the only object here
Panophthalmitis (occurring in blind eye due to old serpiginous ulcer)	Hopeless	2	Immediate relief of pain and inflammation	Enucleation of blind eye greatly facilitated by relief of inflammation
Recurrent corneal ulcer (Leucoma of cornea)	Hopeless due to leucoma	5	Complete, immediate relief of pain; healing of ulcer	Since fever treatment has no benefit on preëxisting scar tissue, the leucoma was unaffected. Further scarring is often prevented in such cases

therapy, and that the remainder would have had serious visual impairment in one or both eyes.

It is impractical, with the number of cases reviewed, to present case reports of all the cases. However, table 2 shows a detailed summarization of 10 typical cases in the excellent or satisfactory groups, selected because they demonstrated the usual response, rather than because they show successful results.

For comparison with the good results demonstrated in table 2, *all* of the unsatisfactory results are reviewed in tables 3 and 4.

Thus we are able to observe that of the

12 cases in which there were more or less unsatisfactory results, the prognosis in 8 was poor or hopeless at the outset. Of the remaining four, two patients refused further treatment. This leaves two patients with good or fair prognosis, of whom one received some benefit and was classed as improved, and one received no benefit at all because there was no particular indication for this type of treatment in that case. The relief of pain in many of these "unsatisfactory" cases not only justifies the treatment but is an immediate benefit not to be disregarded.

It should be noted that of the group of "Relapsed" cases, one patient was

physically unable to continue the treatments, two had ultimate recoveries despite relapses, and one had a relapse related to insufficient treatments, but his final vision was still much improved. Failure to eliminate infectious foci is a great contributory factor in these relapses.

This discussion of the cases not responding to treatment with more than

tion or loss of vision. (3) Photophobia. (4) Lacrimation. (5) Headache.

All of these symptoms are improved by fever treatment. The most dramatic relief afforded is the elimination of pain, usually effected by the first treatment. Lacrimation is also relieved, usually by the first treatment. Headaches and photophobia are next relieved, often by the first treat-

TABLE 4
FAILED, NO VISUAL IMPROVEMENT OR RELIEF OF SYMPTOMS

Diagnosis	Prognosis at Start of Treatment	Number of Treatments Given	Response to Treatment	Remarks
Iritis, acute	Good	1	0	Patient too frightened to coöperate
Panophthalmitis	Poor	8	Slight relief of pain	Treatment given at too low temperatures for good results. Less than 104°F.
Retinitis, chronic	Poor	10	0	No benefit obtained which could be attributed to fever
Laceration of eyeball	Good	1	0	No reason for using fever in this type of case
Choroiditis, acute exudative	Good	1	Some relief of pain	Patient refused further treatment and left hospital

symptomatic improvement bears out the statement made previously that results with fever therapy depend upon early and thorough treatment. If destruction has already occurred the hypertherm can do no more than arrest the progress of the disease. If inadequate treatment is given, the maximum benefit cannot be obtained. In addition to this it is also important that adequate attention be given to infectious foci which may be the cause of, or contributing to, the disease process.

Much has been said of "relief of symptoms" without any specific statement as to the type of symptomatic relief afforded. The chief symptoms benefited by fever therapy in the above conditions are:

(1) Pain in the affected eye. (2) Diminu-

ment, usually by the second or third. The response of vision is varied, and accounts for the reason the treatment was stopped after too short a course in some of the earlier cases. Many patients have rapid visual improvement with the relief of the symptoms of pain and photophobia. Those cases, however, in which there is a plastic exudate, interstitial keratitis, or opacities of the vitreous often do not respond at all, as far as vision is concerned, for several treatments. After the fourth or fifth treatment these cases suddenly begin to clear, and with persistence of the treatment the exudate is absorbed. Absorption may be almost complete if treatment is kept up; if not, some visual defect may remain. The rule is, therefore,

to persist in the treatments, if the patient can tolerate them, for as long as any sign of improvement is present.

The relief of symptoms is accompanied by relief of signs observed by the examiner, as has been mentioned. These signs,

if deep, the healing depends on the duration, and whether they penetrate into the anterior chamber. If relatively recent and uncomplicated, comparatively rapid healing will occur, with no progress or complications of the ulcer other than scar-

TABLE 5
RELAPSE AFTER PYRETOTHERAPY

Diagnosis	Prognosis	No. of Treatments	Response
Sympathetic ophthalmia, Rt. eye. L. eye previously enucleated following iridocyclitis	Poor, vision 20/200	21	Vision returned to 20/30 after ninth treatment but tended to relapse. Further treatment given to prevent relapse. Vision on discharge 20/40. Relapse in three months and patient returned for more treatment
Same case as above	Fair, vision 20/80	10	Vision returned to 20/40 and all symptoms again subsided. Vision will correct to 20/20, and remained unchanged when checked again in six months. Although listed under <i>relapse</i> , the final results were excellent.
Keratitis, traumatic	Guarded, vision 20/120	3	Relief of pain after each treatment, symptoms subsided but relapsed in 10 months. Patient did not have enough treatment according to present knowledge. Patient failed to have infectious foci removed as advised. Final vision 20/40
Keratitis, traumatic	Guarded, vision 20/200	7	Preëxisting central corneal opacity of four years' duration. The acute process was arrested by fever treatment with immediate relief of severe pain. Patient developed mild relapse one month after treatment. Handled by local treatment. Final vision 20/40. Patient failed to have infectious foci removed as advised
Corneal ulcer (duration 13 months)	Guarded	1	Physical condition of patient prevented more than one treatment. Ulcer healed slowly under local treatment and recurred in six months. Not enough treatment to evaluate results

as listed below, are somewhat varied, and, of course, not all related to the same diagnosis: Conjunctivitis. Ulceration of conjunctiva or of cornea. Scarring of cornea. Plastic exudate in the anterior chamber. Hypopyon. Posterior synechia. Inflammation of the uveal tract. Vitreous opacities. Retinitis. Edema of the optic nerve.

Relief of conjunctivitis is rapid. Healing of ulcers is rapid if they are super-

ring. Scarring of the cornea is benefited only in a prophylactic way. Fever therapy in corneal ulcers prevents any more than minimal scarring. Plastic exudate in the anterior chamber, after two or three treatments, is absorbed with amazing rapidity and thoroughness, leaving no residuals in most cases. Relief of posterior synechia depends upon the factors of early treatment and thoroughness, not

only of the fever therapy, but also of the local treatment in the eye. If well handled, excellent results are usually obtained. Inflammation of the uveal tract obtains almost unfailingly excellent end-results, in spite of surprisingly bad cases on admission in some instances. Vitreous opacities, if quite recent, will absorb; but, even when only of moderate duration, are somewhat resistant to treatment. There have not been enough cases presenting retinitis to gain much impression of results. What impression exists is not promising. Edema of the optic nerve subsides relatively rapidly. Since affections of the optic nerve are mostly syphilitic, this sign does not enter into this series, particularly.

Careful handling of these cases by the ophthalmologist is necessary. The usual local treatment measures are continued assiduously, even while the patient is in the cabinet. It is superfluous to enumerate here the various local measures necessary in the care of the eye diseases listed. It is important to stress, however, that these measures must be carried out until healing is complete just as if the patient were not being handled with fever therapy. The purpose of fever therapy is to supplement the standard treatment measures, not to supersede them. The physician in charge of fever therapy and the ophthalmologist must work in constant consultation in almost all of these cases. In this way it is possible to determine the frequency of the treatments necessary, the level of temperature desired, the duration of each treatment, and finally the point at which treatment can be terminated.

It should be emphasized that the danger of this method of treatment is negligible in trained hands, and in this series there were no complications of treatment other than a few cases of mild herpes labialis

after the first treatment, which disappeared after subsequent treatments.

SUMMARY

1. The use of fever therapy by means of the hypertherm cabinet in the treatment of various acute inflammatory diseases of the eye (excluding syphilis) has been discussed. 2. Fifty-two consecutive and unselected cases of various inflammatory diseases of the eye treated in the hypertherm have been grouped by diagnosis and the results examined. 3. Excellent results were obtained in 25 cases, and satisfactory results in 12 cases, giving a total of 37 patients classed as cured. 4. The results in the remaining cases were: Improvement, 7; failure, 5; relapse, 4. These relatively unsatisfactory cases were discussed and certain conclusions obtained. 5. The specific effect of treatment in the relief of the various signs and symptoms was shown to be uniformly good.

CONCLUSIONS

1. The results of pyretotherapy in the treatment of inflammatory diseases of the eye are excellent in many cases, offering the only means of saving partial or total vision.

2. The most striking immediate result of treatment is *relief of pain*. The restoration of vision is slightly more delayed, but very remarkable in most cases, depending on three factors: (a) the duration of the process before the start of fever therapy; (b) the number of treatments given while under the therapeutic regime; (c) the close coöperation of the ophthalmologist, first in persisting in the local treatment, and second in determining the point at which treatment is to be discontinued.

3. It is evident that much vision may be saved by this method of therapy, and

equally evident that it is not applied as much as possible even where it is available. It is desirable, therefore, that ophthalmologists become more aware of the usefulness of this therapeutic method, and ascertain the means at hand in their locality whereby they may make it rapidly available to selected patients.

The authors wish to acknowledge with appreciation the various contributions made by the following doctors: Dr. J. Trautman, and Dr. W. A. Paget, of the United States Public Health Service; Dr. William M. Boles, Dr. H. F. Brewster, Dr. W. R. Buffington, Dr. William B. Clark, all of New Orleans, Louisiana.

JUVENILE CATARACT IN ASSOCIATION WITH DERMATOSIS*

(CATARACTA SYNDERMATOTICA)

DANIEL M. ROLETT, M.D.

New York

From the time that Rothmund¹ in 1868 described the occurrence of juvenile cataracts associated with a peculiar skin degeneration in a family of two brothers who married two sisters, the interest of the medical profession was aroused. So far 37 cases have been reported in English and European literature. Of these, 15 were published in America, 20 in Europe, 1 in Australia, and 1 in England.

Evidently they are not frequent, and the purpose of this paper is not only to present another case but to bring out the characteristics of this unusual disease that affects the skin and the lens.

The outstanding symptoms of the disease are marked generally but not universally by:

1. Endocrine disturbances²
2. Skin pathology diagnosed as
 - a) Scleroderma
 - b) Neurodermatitis
3. Lens pathology

Of the endocrine-gland disturbances the most prominent are: Infantilism, poor body growth, premature graying of hair, underdevelopment of sex organs, and abnormal basal metabolism. Of the endocrine glands involved, the most common are thyroid, parathyroid, testicular and ovarian glands, although undeniably some of the cases show evidence of pluriglandular disturbance.

As seen from the cases reported in the literature, endocrine disturbances were observed 16 times, graying of hair in 8 cases, scleroderma in about 55 percent of cases, and neurodermatitis in 45 percent.

* Read before the New York Clinical Society for Ophthalmology, February 1, 1943.

One must be particularly careful to differentiate the juvenile type of cataract known as cataracta syndermatotica, from the cases of cataract occurring in association with hypofunction of the parathyroid gland. The term *syndermatogenous cataract* was suggested by Kugelberg³ in 1934, because the cataractous lens changes occur in association with abnormal skin changes.

It is well known that in endocrine disturbances such as tetany, myxedema,⁴ disturbances of the sex-organs' function,⁵ and in cases of myotonic disturbance⁶ we are likely to find cataracts. These, however, differ from the juvenile cataracts which occur in association with the skin changes in Rothmund's disease.⁷

Of the skin changes, *scleroderma*, quite commonly found in Rothmund's disease, but not the cause of it, is itself of unknown origin. Some of the authors attribute it to

- (a) Endocrine disturbances — Hoffman⁸
- (b) Primary vascular disease—Kraus⁹
- (c) Damage to vegetative nerve centers—Curshmann¹⁰
- (d) Peculiar skin predisposition, aggravated by exogenous toxins (infection), trauma, exposure to cold and wet, and changes in the vascular system—Barkman¹¹

It is characterized by a chronic localized or diffused induration and rigidity of the skin, which is tense, leatherlike, and cannot be pinched or lifted up, for it is bound down to the underlying structures. Associated with it is atrophy of subcutaneous fat and glands due to the pressure.

from increased fibrous and connective tissue. These changes mostly involve the breast, neck, forearms, and lower extremities. When the face is involved, facial hemiatrophy results (lack of expression).

Neurodermatitis, the next important symptom of the disease, is found in somewhat less than 50 percent of the cases. It is characterized by severe protracted itching, and a chronic eczema extremely obstinate to treatment, involving the face, the neck, and the flexor surfaces of the extremities. It is especially pronounced in the folds of the skin, resulting in a thickened, scaly, and eczematous condition. The face, because of lack of the usual folds and the grossly exaggerated thickened state, takes on a characteristic leonine appearance. The disease is not uncommonly associated with bronchial asthma and other allergic phenomena.

According to Ehrmann¹² the cause of neurodermatitis is primarily an endocrine disturbance involving the thyroid, ovarian, and pancreatic glands individually or severally. Last, but not least, it may be the result of digestive disturbances (chemical changes, interference with proper function of the Islands of Langerhans or mechanical motility of the bowel) and acid or subacid condition of the stomach.

Strandberg¹³ agreed with Ehrmann that abnormal products of decomposition, not properly eliminated, become absorbed into the blood stream thereby resulting in irritation of the peripheral skin nerves, dermatographia, urticaria with severe itching, and lead finally to an eczematous condition of the skin because of constant scratching.

On the other hand, numerous other authors, among them Urbach,¹⁴ are more conservative and cautious in expressing their opinion as to the cause of neuro-

dermatitis. They believe it to be a peculiar disturbance of the vegetative nervous system.

However that may be, it is by now clear that the causes of scleroderma and neurodermatitis are different. Although both may accompany the peculiar juvenile cataract in various individuals, it does not follow that either of the skin diseases is the cause of the cataract, but rather another symptom of the same disease.

The most characteristic symptom of Rothmund's disease is the lens changes. The lens opacity consists of numerous grayish-white dots of varying sizes which tend to become confluent in the central portion of the lens and scatter more diffusely toward the periphery. The posterior cortex is never so extensively involved as the anterior, and no cholesterol deposits are found as a rule, although Loewenstein¹⁵ found multicolored cholesterol deposits in his case. Usually the nucleus of the lens is poorly visible, although it is unaffected. The main opacity is located axially in the anterior cortical layers, involving the superficial layers up to the capsule. Some authors claim that, on the whole, the morphologic picture of this cataract presents a remarkable resemblance to the cataracts caused by massive doses of X ray.¹⁶

In the following table an attempt is made to compile most of the specific cases described in literature thus far, clarifying them according to their outstanding symptoms.

From these tables it can be readily ascertained that scleroderma is the most common skin lesion, that prematurely gray hair is a quite common symptom, and that thyroid dysfunction is not at all rare.

CASE REPORT

C. B., a young man about 20 years of age, came with the complaint of a rapid

ance was striking. The face, especially the forehead, the cheek, and the ears were coarse, dry, and scaly and lacked the usual folds, giving him a leonine expression. The skin of the rest of the body was likewise thickened, coarse and dry, with a lack of folds on the flexor surfaces. There was complete absence of hair on the abdomen; it was sparse in the axillae and arranged in a feminine way near the pubis. The sexual organs were small and undeveloped for the size of the body.

Laboratory tests gave the following results: Red blood corpuscles, 4.5 million; white blood corpuscles, 4,800; relative lymphocytosis, 16 percent eosinophilia. The blood chemistry was negative, as was also the urinalysis and the Wassermann reaction. The basal metabolism was -7.

Eye examination. The lids of both eyes

were thickened, dry, and scaly. It was almost impossible to evert the lids manually. The conjunctiva of the lids was thickened, that of the eyeball was of normal appearance. The cornea was clear, the anterior chamber somewhat deeper than normal, the iris normal.

The lens showed subcapsular freely scattered opacities involving mainly the central portion of the anterior cortical layer, although the posterior layers were also involved, but not so much. The opacities were densest at the axis of the lens. Toward the periphery the opacities became rather thin and scattered. There was a free zone at the extreme periphery of the lens. The vitreous was not clearly visible and the fundus was likewise not seen. The cataract of the right eye was far more developed than that of the left.

Vision: O.D. without correction was 20/200; with a +0.75D. sph. = 20/200;

O.S. without correction 20/100; with a +0.50D. sph. = 20/70.

Operation. Cataract extraction was performed on both eyes at a six-month interval and consisted of a discission and five days later a keratome incision with irrigation of the soft lens matter.

Final result. Vision 20/20 in each eye with correction.

CONCLUSION

The important points to be remembered in Rothmund's disease are:

1. Occurrence of cataractous changes in rather young people with typical skin

changes which may or may not arise simultaneously.

2. Evidence of pluriglandular endocrine disturbances.

3. Skin changes although bearing a similarity are not always of the same origin and are not therefore the cause of the disease.

4. The development of the cataract is rapid and progressive.

5. The prognosis as to the operation and subsequent vision is favorable.

6. Fortunately the disease is not common.

876 Park Avenue.

CHOLESTERINOSIS LENTIS*

PIERRE GEORGARIOU, M.D., AND OTIS WOLFE, M.D.

Marshalltown, Iowa

Cholesterinosis lentis constitutes a particular form of cataract of which neither the etiology nor the pathogeny is clear. It is first necessary to differentiate between this type and other similar types of cataracts. The latter are: (a) Calcareous cataract, which is milky white in color and does not have the shining appearance of cholesterinosis lenti. (b) Xanthomatosis lenti,¹ which presents widespread fatty deposits without particular form and appears only in young people. Etiologically it is in very close relation to Niemann-Pick's disease. (c) Hypermature cataract, the result of the proteolysis of the necrotic lens mass, appearing white or yellowish in color, with cretaceous deposits scattered throughout. (d) Diabetic subcapsular cataract, which is characterized by pathognomonic subcapsular changes in the posterior cortex. It is always bilateral and most frequent in young people.

In cholesterinosis lentis brilliant crystals appear in the posterior cortex of the lens, irregularly deposited. It is usually unilateral and appears at any age. Knowledge of the pathology of this type provides us with very valuable information for clinical observations.

How does cholesterol appear in the lens?

Is it an element in composition that appears after a disturbance in the lens or is it an element that is transported from without with the nutritious matter?

It was in 1831 that Schmidt² first noticed the presence of the cholesterol crystals in the anterior chamber of a patient and wrote, "From the frontal surface of a white cataract, there seems to liberate

itself, a shining powder, golden and very fine, which, trembling at first in the aqueous, falls like a thick carpet on the inferior surface of the anterior chamber." Since then it seems that all authors agree that the cholesterol originates in the crystalline lens. All relating publications (Poncet,³ Königstein,⁴ Desmarres,⁵ Folin,⁶ Scholer⁷ arrive at the same conclusion: "Upon rupture of the lens capsule, cholesterol is deposited in the anterior chamber." As an explanation of this opinion, Jacobsen⁸ in 1881 set forth that the cholesterol cannot possibly be a component which was transported through its nutrient matter to the crystalline lens, but was the product of a regressive metamorphosis of its albumin after a delayed absorption (Heilborn,⁹ 1915). However, some of the experimental workers, such as Blassius,¹⁰ Besserer,¹¹ and Heilborn,⁹ have seriously questioned the existence of cholesterol in the lens. On the contrary there are important investigators such as Zehlender, Mathessen, and Jacobson,¹² representing earlier writers, and Kawarura¹³ among the contemporary authors, who state with assurance that the normal crystalline lens contains cholesterol. Adams,¹⁴ Neushiller,¹⁵ Cahane,¹⁶ and Salit¹⁷ found in human cataractous lenses more than 0.25 percent cholesterol. Salit and O'Brien¹⁸ accepted as positive the fact that there is a significant increase of cholesterol, both in aged and cataractous lenses. The strongest proof was advanced by Vogt,¹⁹ who discovered that not only in complicated cataracts, but also in senile types, the formation of large cholesterol spots is not a rare occurrence. Lately, Sugita,²⁰ while examining a series of extracted cataracts, found fat deposited in

* From the Eye Department, Evangelical Deaconess Hospital.

the form of fine droplets in all parts of the lens. Joschichara²¹ also noticed in a congenital cataract numerous cholesterol substances that appeared in the dark field when examined under the polarization microscope.

In spite of all these opinions, it may be said today that it has not been clearly proved that the chemical basis of this cholesterol is contained within the normal crystalline lens. It is known only that under certain conditions the lens is capable of presenting parts of local cholesteatosis. Chemicobiologically, only, is it certain that "The essential lipoids (phospholipoids, cholesterol) are necessary for the life of the cells and these substances presumably have some biological significance, of which we are, as yet, ignorant. It may be that the increase in fat is a secondary occurrence comparable to the common process of fatty deposition occurring in senile and degenerating tissues generally, depending essentially on a lessening of oxidative activity" (Duke-Elder²²).

What is the pathogeny of these cholesteatosis?

An explanation may be derived from facts based upon known clinical and experimental evidence.

It is known that the crystalline lens possesses, among other elements, a quantity of lipoids. It is clear from the famous works of Goldsmith²³ that the lipoids increase, at an advanced age, following an alternating chemical play that occurs in the crystalline lens between the cysteine and the cystine. Actually, if any cataract is very carefully examined biomicroscopically, small drops of lipoids or fine elements of cholesterol will be discovered in the crystalline masses in about 80 percent of the cases. Other changes of the colloids and lipoids within the crystalline lens that present cholesterol elements are found in coronary cataract, rosette cataract, mature cataract, in various types of

senile and lamellar cataract, in nuclear cataract and various manifestations of cataract incipiens posterior. If we deny, then, even the actual existence of cholesterol in the crystalline lens, we can obtain it indirectly after a regressive metamorphosis or after a disturbance of these lipoids. But what is the pathogeny of this disturbance of the crystalline-lipoid complex, and what are the conditions that act to produce it?

The theories of the pathogeny of cholesterolinosis bulbi and lipoidosis bulbi have already been proved by one of us (P. G.²⁴). In lipoidosis bulbi there must always have preceded a prolonged irritation of the corpus ciliaris or of the iris. This irritation causes alterations in the adjacent tissues, in the form of an infiltrative lipoid degeneration. This localized disturbance of the lipoid complex produces the appearance of cholesterol crystals in the form of an exudate as a secondary sign. Before attempting an explanation of the pathogeny of cholesterolinosis lentis, it must first be determined whether hypercholesterinemia could be a causative factor. There are many experimental investigations by Aschoff,²⁵ Versee,²⁶ Jesse,²⁷ Huth,²⁸ Röhrschneider,²⁹ and Joel³⁰ that have sought an explanation of this theory. All of these workers have concluded that, in animals, hypercholesterinemia can produce the appearance of cholesterol in the eye. However, after a long series of experiments one of us (P. G.³¹) has demonstrated that in man hypercholesterinemia does not produce the appearance of cholesterol in the human eye.

Turning now to an explanation of the pathogeny of cholesterolinosis lentis—that is, an explanation of this shining image with the small and large crystals placed one upon the other without definite form—two points immediately attract the attention of the examiner: 1. The cholesterol-

in crystals are always placed in the posterior half of the crystalline lens. 2. There always exists, at the same time, an alteration of the lens capsule.

These two clinical facts in relation to the aforementioned theory give a very clear pathogenic explanation. The first cause of this always exists outside the crystalline lens. An infiltrative alteration of the ciliary body, the zonula, or of the vitreous body (possibly after long irritation) can cause a relative alteration in part of the posterior crystalline lens. This alteration of the capsule appears like a fatty infiltration of this membrane. Secondly, it is dependent upon the intensity of the alteration before the crystalline masses suffer a disturbance in their lipid complex. The result of this disturbance is the appearance of the cholesterine under the phase of local cholesteatoses.

In reality, if one observes a sufficient number of cases, it will be proved that behind or adjacent to the central part of the cholesteatosis, the crystalline capsule is always altered; either infiltrated or swollen. This alteration is not primary in nature but secondary. Definite proof of this is to be obtained by examining the eye, and particularly the corpus vitreum, the ora serrata, and the corpus ciliaris in so far as possible, and, in general, all parts that surround the crystalline lens, in order to prove that other alterations are primary signs. It is of great importance that the examiner persist in a detailed examination of the corpus ciliaris. The examination should always be made with the contact glass that will allow the perception of the finest alteration of these internal structures. Troncoso³² and Trantas³³ have presented lengthy discussions on the advantage of contact glasses for a detailed examination.

Cholesterinosis lentis is always a cataract of secondary nature, for it is brought about by changes outside the crystalline

lens. Retinosis pigmentosa, retinitis haemorrhagica, iridocyclitis, and uveitis are conditions most often causing cholesterinosis lentis. There is another condition that probably brings this about more often than the others, and that is highly toxic cyclitis latens. This inflammation of the corpus ciliaris is so slow that it is often developed, in many cases, without pain and lacking in clinical symptomatology.

It is possible that simultaneously with the advancement of the infiltration of the crystalline capsule, there is present an incipient cortical or lamellar or perinuclear cataract (in elderly patients). This disturbance of the crystalline-lens composition favors, without doubt, the interference of the lipid complex and causes the appearance of cholesterin crystals, more quickly and in greater quantities. In two previous works one of us (P. G.²⁴) has explained the pathogeny of the appearance of cholesterin in the anterior cortex of the eye as well as in the posterior cortex. The conclusions reached can explain the cholesterinosis of the lens because of the fact that cholesterin crystals appear in the iris, the anterior chamber of the cornea, the hyaloid, or the retina after a sustained irritation of the corpus ciliaris or its adnexa.

SUMMARY

1. Pathogenic explanation of cholesterinosis lentis is based upon the pathogenic theory of lipoidosis bulbi. Conditions found outside the crystalline lens produce an infiltration of the posterior cortex of the crystalline-lens capsule. This infiltration follows a secondary disturbance of the lipid complex of the crystalline masses, producing the appearance of shining crystals of cholesterin.

2. Cholesterinosis lentis is always a secondary cataract, and we should persist in detailed examinations to discover the primary causative factor.

NOTES, CASES, INSTRUMENTS

ERYTHEMA NODOSUM EPISCLERITIS

A CASE REPORT

EUGENE W. ANTHONY, CAPT. (MC),
A.U.S.

AND

DON MARSHALL, MAJOR (MC), A.U.S.

A brief discussion and bibliography on this subject may be found in Duke-Elder's, "Textbook of ophthalmology."¹ One case in the English literature was reported by Green and Perry in 1939.²

One month prior to his admission to the hospital on March 15, 1943, the patient was off duty for four days because of fever and sore throat. On March 8th, he developed pain in both hips and the lower back, which made walking difficult. On March 14th, tender red spots appeared over the anterior and medial aspects of both legs. There was no previous history of arthritis, rheumatic fever, or skin eruptions.

The physical examination on admission revealed redness and exudate on the left tonsil, tenderness over both knee joints, and several moderately large, red, swollen nodules over the anterior aspects of both lower legs, typical of erythema nodosum. Temperature varied daily between 100° and 103°F.

The laboratory findings of March 16th were: Blood count, R.B.C. 4,940,000 with hemoglobin 85 percent; W.B.C. 13,750; 73 percent polymorphonuclears, 23 percent lymphocytes and 4 percent monocytes; electrocardiogram, normal; X-ray film of chest, normal; Kahn test, negative; blood sulfa-drug level, zero; blood cultures, no growth; Widal and undulant fever reactions, normal.

Salicylates were given for the first 5 days, with an average daily dose of 80

grains. Little improvement resulted in either symptoms or temperature, and the drug was discontinued on the sixth day. In the next 24 hours the patient received 120 grains of sulfathiazole and 40 grains of sodium bicarbonate. After the first few doses of this drug the patient became nauseated and vomited forcefully. The joint symptoms became worse, and a small macular rash appeared on both hands. The eyes were somewhat irritated and it was noticed that they were slightly red.

Ocular examination: Examination on March 23d revealed involvement of the external and internal bulbar conjunctiva of both eyes. There was no redness of either palpebral conjunctiva. The lesions consisted of several small, raised, yellowish nodules surrounded by deep redness fading into a pink and then finally surrounded by a slight bluish flush. The largest nodule was in the right outer angle and measured about 1½ mm. in diameter. There was a small subconjunctival hemorrhage in this region extending 3 mm. from the limbus. Pressure on the lid over these areas revealed slight tenderness but no pain. The nodules were movable on the sclera. The drawing shows the relative size and location as compared with the cornea (fig. 1). Above and below the cornea the bulbar conjunctiva was completely normal. Cornea, iris, lens, media, and fundus were normal upon bedside examination with loupe and ophthalmoscope.

The sulfathiazole was discontinued on March 23d, and the salicylates resumed as before. The macular eruption on the hands disappeared the next day. Three days later, on the 26th, the hyperemia of the inner angles was much diminished, but the nodules could still be made out. There

was still moderate hyperemia of both outer angles. Most distinctive was the yellowish discoloration present in the subconjunctival tissue, extending laterally and medially from the limbus about 9 mm. and fading into a faint bluish haze. The nodules were smaller but easily visible on top of the yellowish discoloration. The patient was comfortable except for some

nor exacerbation of either the eye signs or the erythema nodosum. The sulfathiazole was not resumed at this time because of his physical discomfort. Salicylates were resumed and again he clinically improved. On April 14th he was placed on 90 grains of sulfadiazine daily, so that on the 21st and 23d he had a blood level of over 8 mg. percent. No untoward symp-

Fig. 1 (Anthony and Marshall). Erythema nodosum episcleritis.

slight joint pains and the red sore eruptions of the legs, which were subsiding.

On March 28th, the outer angle of the left eye was nearly clear with the exception of a moderate yellowish color. Nodules could still be made out in the other areas, the right outer angle showing the least improvement. The small subconjunctival hemorrhage of this area was partially absorbed.

The yellowish discoloration was the last sign to disappear, and the eyes were again normal on about April 7th, two weeks after the first observation. It was also at about this time that all signs of the nodules on the legs disappeared.

To determine if the eye lesions might reappear, all medication was stopped on the 29th of March for a period of 32 hours. The patient became very uncomfortable, with marked increase in joint symptoms and a rise in temperature from 100° to 103°F. There was no recurrence

toms resulted and no special improvement occurred.

His general condition improved very gradually and occasional evening temperature rises were present until the middle of June. In view of the convalescence required, following three months in bed, he was transferred to an Army Hospital in the Zone of the Interior.

DISCUSSION

One might suggest that the ocular lesion was caused by a sensitivity to sulfonamides. However, the eye changes persisted for two weeks after withdrawal of the drug and were not reproduced by later use of another sulfonamide. It would seem that the lesion was aggravated by the withdrawal of the salicylates not unlike the exacerbation that occurred in the joints. The ocular signs reported by Green and Perry, in 1939, are almost an exact

duplicate of those seen in this case, and occurred in a patient having erythema nodosum. No sulfa drugs were used in their case.

PRIMARY MENINGOCOCCIC CONJUNCTIVITIS TREATED BY SULFADIAZINE

PHILLIPS THYGESON, LT. COL. (MC),
A.U.S.

Drew Field, Florida

Endogenous meningococcic conjunctivitis occurs as a rare complication of epidemic meningitis. Still more rare is exogenous meningococcic conjunctivitis uncomplicated by general symptoms. While numerous reports in the literature attest the favorable effect of the sulfonamides on meningococcic meningitis, no reference as to their effect on exogenous meningococcic conjunctivitis has appeared as yet. For this reason the following case report would seem to be of interest.

Report of case. W. T. S., a young white man, aged 21 years, was admitted to the Station Hospital, Drew Field, Florida, on March 27, 1943, with German measles of one day's duration. There was a typical punctate rash with posterior auricular-node enlargement. The rash disappeared on the fifth day after admission, and the patient appeared to be well on April 1st. At no time were there any ocular signs or symptoms.

On the evening of April 2d the onset of a bilateral conjunctivitis was noted by the nurse in charge, and when seen by the writer on the morning of April 3d the patient exhibited a severe bilateral acute purulent conjunctivitis. The conjunctiva showed marked papillary hyper-

trophy, and there was a profuse purulent discharge. Both corneas were clear. Gram-stained smears of the exudate showed predominant polymorphonuclear leucocytes and many typical Gram-negative intracellular diplococci of gonococcus-like morphology. A tentative diagnosis of gonorrheal ophthalmia was made, and the patient was examined for evidence of urethral gonorrhea. No previous history nor evidence of the disease was found, however, and the patient denied having had any recent sexual contact. Treatment consisting of full doses of sulfadiazine by mouth, combined with boric-acid-solution irrigations every two hours and followed by instillations of 5-percent sulfathiazole ointment, was instituted.

On April 5th both eyes showed distinct improvement, and the discharge had become scanty. By April 12th, the conjunctival secretion had stopped but there was still some slight residual inflammation. On April 16th, the cultures taken on the second day of the disease were reported to be meningococcus, and this diagnosis was later verified by the laboratory of the Fourth Service Command. On April 20th, after three successive negative smears and cultures had been obtained, the sulfadiazine and local eye treatment were discontinued, and the patient was discharged on April 25th. Vision was 20/20 in each eye, and the conjunctiva had returned to normal.

The sulfadiazine treatment consisted of an initial dose of 2.0 gm. followed by 1.0

gm. of the drug every four hours day and night, combined with an equal amount of sodium bicarbonate, for the first four days. After this the sulfadiazine and bicarbonate were reduced to 1.0 gm. four times daily for the remainder of the treatment period. Blood levels varied from 3 mg. percent to 20 mg. percent, but averaged 6 mg. percent. The blood picture remained normal during the treatment period. A throat culture taken on April 14th was negative for the meningococcus. There was no febrile reaction at any time during the course of the disease.

COMMENT

The conjunctivitis responded rapidly and satisfactorily to sulfonamide therapy, and no extensions to the blood stream or to the meninges occurred. The rapidity of the response was comparable to that seen by the writer in sulfonamide-treated cases of gonorrheal ophthalmia.

The source of the infection was undetermined, but it may have been a ward contamination, since two cases of meningococcal meningitis were under treatment at the time that the patient was confined with German measles. These cases were isolated in separate rooms, however, while the patient under discussion was kept on the ward. During the previous two months sporadic cases of meningococcal meningitis had been appearing on the Field.

The reported case well illustrates the necessity of examination by culture of Gram-negative diplococci in purulent conjunctivitis to make a differential diagnosis between gonorrheal ophthalmia and primary meningococcal conjunctivitis, which may be clinically indistinguishable. Needless to say the medicolegal and social consequences of confusing them are potentially very great.

Station Hospital.

UNUSUAL EYE FINDINGS IN IDENTICAL TWINS*

G. M. CONSTANS, M.D.

Bismarck, North Dakota

Similar eye findings are of interest in individuals, still more in identical twins. Attention has been drawn to this by the not-infrequent reports in the literature. This additional report is published to note the similar eye findings in identical boy twins due to congenital factors.

One was seen at the age of five months because of cleft palate, and the other at the age of four years. They had similar eye findings of high compound myopic astigmatism in their right eyes and congenital complicated cataracts in their left eyes. One subsequently had a detached retina in the right eye.

Their deliveries were normal, and there were no congenital defects except those described.

There were two other children in this family, both older. A sister, aged seven years, was seen in December, 1942. She presented a high myopic astigmatism, the vision without correction being 1/60 in each eye. When corrected, the vision was 6/20 + 1 in each eye with a -10.00D. sph. \approx -0.75D. cyl. ax. 180° for the right eye and a -10.00D. sph. \approx -1.25D. cyl. ax. 180° for the left eye. She was mentally alert and exhibited no other physical defects, although both fundi showed pallor of the discs with retraction of the scleral rings, which is often seen in high myopia.

A brother, aged nine years, was seen at the same time as the sister. He had progressed normally in school and was in good physical condition. His vision was 6/18-1 in the right eye and 6/15 in the left eye, without correction. He had a

* From the Department of Ophthalmology, Quain and Ramstad Clinic.

compound hyperopic astigmatism and was wearing a $+0.50D.$ sph. $\approx +0.50D.$ cyl. ax. 90° for the right eye and a $+0.75D.$ sph. $\approx +0.50D.$ cyl. ax. 90° for the left eye; this correction brought his vision to 6/6.5-2 in the right eye and 6/6 in the left. The fundi were normal.

The father was interviewed, but not examined. He stated that he had never had any difficulty of vision, nor had any of his family.

The mother has poor vision. Her home life is incompatible and she is now in the State Hospital for the Insane. As far as can be determined her family history is negative. A report on her condition from the State Hospital ophthalmologist is as follows:

"Vision is very poor. The right eye reveals a high myopia, fluid vitreous with opacities, cataractous lens, partial detachment of the retina, and degenerative choroiditis resembling luetic type. The left eye reveals a similar condition except that the lens is dislocated temporarily. Iridodonesis is present, and the retina is not detached."

The blood-Wassermann test was positive and the spinal fluid negative in 1942. Her diagnosis is schizophrenia, paranoid type, and latent syphilis.

As stated before, one twin, Elmer M., was seen in the Clinic for congenital cleft palate involving the posterior two thirds of the hard palate, the entire soft palate, and the uvula. This was repaired by means of a two-stage operation at the ages of three and four years, with complete cure. This boy had a speech defect from this condition with some mental retardation as noted by a psychologist. Both conditions improved after surgery was performed. The general physical findings, including urinalysis, blood examination, Kahn and Wassermann tests, were negative with the exception of hy-

pertrophy of the tonsils and adenoids with chronic infection. This patient subsequently had his tonsils and adenoids removed and preputial adhesions loosened.

A peculiar eye condition was observed prior to the first operation on the palate, and the child was seen in consultation by the Eye Department three years later, on January 13, 1941. The eye findings were as follows: Vision was not obtained. The eyelids were normal externally and opened and closed freely. The ocular movements were unimpaired. The conjunctiva and cornea were clear. Tension was normal to palpation. The fields were not obtained. The pupils and reflexes were normal. In the right eye the fundus showed a high myopia with pallor of the disc and retraction of the scleral ring. In the left eye the pupil was small, reacted poorly, and was occluded; the fundus could not be seen. The lens was cataractous, congenital in type.

The left eye was operated upon, a crucial discission being performed. The membrane was leathery, calcified, and nearly impossible to cut. Seven months later, iridectomy and linear extraction of the lens were performed. The mass was adherent to the iris, and after extraction a grayish membrane (the posterior capsule) persisted. This was incised and a serosanguineous fluid obtained. There was no loss of vitreous. Seven-and-one-half months later a V-shaped discission was performed. The membrane was thick, difficult to cut, and did not retract. No improvement in the vision was noted, and the fundus never could be seen. Further operative procedure was abandoned.

The right eye was refracted, and when last seen on August 20, 1943, the patient's correction was a $-13.50D.$ sph. $\approx -1.25D.$ cyl. ax. 180° , and the vision was 2/60.

The second twin, Albert M., four years

old, was seen on March 19, 1942, because of poor vision. His general physical examination, blood studies, urinalysis, Kahn and Wassermann tests were negative. There was no deformity of the palate, but hypertrophied tonsils with obstructing adenoids were present together with a phimosis. He had surgery for these conditions with a good result.

His vision was poor. The eyes were normal in size, shape, and position. The lids opened and closed freely, the ocular movements were unimpaired, and the conjunctivas and corneas were clear. In the right eye the pupil was round, it dilated well under cycloplegia, and responded to light, in accommodation, and convergence. The media were clear. The fundus was myopic and showed pallor of the disc. The patient was given a prescription of $-18.50D.$ sph. $\approx -2.50D.$ cyl. ax. 180° for the refractive error in his right eye.

Externally the left eye was negative. The pupil was fixed and occluded, but reacted slightly to light. The lens was cataractous, and the fundus was not seen.

Discission was attempted. The lens could be moved, but could not be cut through. The findings were similar to those in his twin brother's eye, and further surgery was not done. This boy got along well until November 2, 1942, when his father stated that he suddenly lost his sight in the right eye. When seen, the pupil was dilated, but reacted. He had light perception, but no light projection. There was a nearly complete detachment of the retina from the 1- to the 6-o'clock position temporally, involving the macula and most of the disc. The vitreous was hazy. The prognosis was poor.

Reattachment was attempted on November 6, 1942. One month after dismissal from the hospital the patient could see moving objects. There was some reattachment, but the vitreous was so cloudy

that the fundus could not be seen well enough to undertake further operative procedure.

Albert M., last seen here on August 20, 1943, had slight light perception, but no light projection. The lens was hazy and there were posterior corneal opacities. The vitreous was cloudy and the fundus was not seen.

The boys are now mentally alert and in good physical condition. They have been sent to the State School for the Blind for instruction.

In view of the findings in the mother's case, the conditions were undoubtedly congenital and probably inherited. There is no hope of vision in the eyes with the congenital cataracts, which probably have a congenital degeneration as well. The prognosis for the myopic eyes is poor, as this condition is, no doubt, due, in part, to a defect in the germ plasm. It may result in a detachment of the retina in the twin Elmer M. as it did in his brother's case, although his myopia is not so great.

Quain and Ramstad Clinic.

A MODIFIED FILM ADAPTER FOR RETINAL PHOTOGRAPHY*

FERDINAND L. P. KOCH, M.D., AND
ARTHUR F. WILLIAMS
Saint Paul

Those who prefer the bantam film pack for photography of the human eye-grounds, whether for color or for black-and-white delineation, have been compelled of necessity either to design their own film carriers or to rely on the Rollex adapter^{1, 2} (figs. 1, 2, 3). The expense of the former commonly does not justify

*From the Department of Ophthalmology and Otolaryngology, The Medical School, The University of Minnesota, Minneapolis.

Fig. 1 (Koch and Williams). Rollex adapter in place at end of tube in plane of photographic layer with focusing eyepiece of Zeiss-Norden retinal camera above.

the results obtained, while the latter possesses inherent vagaries that are directly attributable to the lack of sturdy precision construction. The hinged outer shell, or housing, usually gives satisfactory service, but the inner film holder proper, which is removable from the housing, has

several faults each of which may be responsible for, or is causal to, the tearing of the film strip and the subsequent loss of the exposures made.

The unmodified body, or holder, or the adapter is simple in design and construction: Each of two light metal rollers situated close to the base at each end is maintained in position by means of permanent insertion of the roller ends into a depressed axle hole on each side of each end of the base of the holder; however, these rollers unfortunately are not cushioned either by bushings or bearings. This lack results in a gradual and irregular enlargement of all four axle holes as the adapter continues in use. This, in turn, causes irregular alignment and subsequent eventual tearing of the film strip.

The holder, as well as its two parallel vertical sides, is stamped from thin light metal approximately 0.5 mm. in thickness. The sides arise from the flat base at an angle of 90 degrees and the film itself is so maintained in the holder that the metal roll, or spool, on which the film is packed is positioned just above but slightly inward from each of the two rollers over which the film travels. The film is brought around underneath the holder so that the free end can be carried

Fig. 2 (Koch and Williams). Rollex adapter housing to left and film holder proper to right. Fig. 3. Detail of film holder of Rollex adapter showing empty bantam spools with reducing studs at each end of each spool. Hand-turning key is seen at lower right-hand corner of holder.

up and forward and locked into the forward spool the rotating movement of which is initiated and controlled by a small, hand-turning key. The latter can rotate only in a counter-clockwise direction. The key rarely is able to withstand the relatively extreme force necessary to effect progressive movement of the film when the latter is subjected to

shear off, and this constitutes another annoying structural weakness that must be considered together with those already mentioned in designing a new film holder or in modifying the fairly commonly used Rollex adapter.

One of us (F. K.) in conjunction with Mr. Kern Larkin of The Institute of Ophthalmology, New York City, found

Fig. 4 (Koch and Williams). Film holder of sturdy brass construction, in place in housing. Bright surfaces proved to be unsatisfactory. Designed in conjunction with Mr. Kern Larkin. Fig. 5. Modification of film holder, or carrier, showing detail of thin spring strip above for support of forward spool to the right and the supporting hooked loops for the rearward spool to the left. These new parts ordinarily are blackened with dull lacquer but they are shown here in white for clarification.

stresses occasioned by irregularities of the holes in which the rollers turn on their axes. The film spools are seated in small stamped-out grooves that do not permit of their easy rotation. The forward spool locks into position by means of resistance furnished by a very weak spring seat at the end of the spool opposite the turning key.

The holder accommodates 127 film without the use of studs, as Bogart³ recently has pointed out; however, when 35-mm. film is to be used it is always necessary to insert studs, or reducing ends, at both ends of each spool. These studs carry small, protruding restraining pins which are received into the ends of lengthwise open slots in the spools, but these pins not infrequently break or

it expedient, several years ago, to construct a film holder that appreciably increased spring-seat resistance and prevented slipping of the forward, or activating, spool while undergoing rotation (fig. 4). This greatly reduced the loss of film from mechanical disabilities but, since greater strength had been obtained by the use of a heavy, rigid brass base, another difficulty arose: It was not feasible to effect a properly dull patina or to oxidize inexpensively the gleaming brass surface. Painted finishes tended to flake and chip. It became necessary to develop an entirely new table of amperage and exposure values because the antihalation properties of the color film were not always sufficiently adequate to obviate retroillumination from the underlying

brightly reflective surface of the new holder.

It seemed desirable, then, to incorporate these same features of sturdiness into the base supplied as an integral part of the Rollex adapter. This we believe we have accomplished without the use of additional important metallic materials and without increasing appreciably the weight of the device; nor have we sacrificed the blackened, or oxidized, surfaces of the original holder proper. The changes may be effected in any even only modestly equipped instrument shop.

Our modifications have been effected by drill-punching into previously determined positions six to eight small, additional pieces of metal five to seven of which, respectively, may be fabricated from any light-weight alloy at hand but one of which should be tempered ferrous metal since it is utilized as a spring strip. The latter is patterned to comma-shape to form a rearward rectangular base and a flat, ovoid, spatulate forward end. Onto the inner surface of this ovoid end there is rivet-mounted centrally a small, rounded nubbin, 5 to 6 mm. in height. This snugly receives the open end of the film spool opposite the turning key and takes the place of one of the reducing studs previously mentioned. The ovoid, forward end of the spring strip narrows downward and backward at a 20-degree angle into a continuation of the strip the bottom edge of which closely juxtaposes the inner surface of the base of the holder proper. The outer surface of the rearward end of the strip is applied to a small, flat, rectangular metallic block which, after riveting, holds the strip 3 mm. inward from the lower inner surface of the side of the holder. This position is permanently secured by through-and-through punch-riveting the strip, block, and side of the holder. The forward end of this spring then is free and

elevated and parallel to the side of the holder, so that the forward spool rotates easily against the firm resistance offered by the unanchored spatulate end of the spring strip (fig. 5). It is necessary, however, to interpose one reducing stud between the socket of the turning key and the end of the film spool itself.

The rear spool is held securely in place by punch-riveting a curved, hooked piece of metal onto the upper inner surface of the rearward one third of each vertical side of the holder. These two small pieces are so fashioned as to provide a forward, flat rectangle from the rear end of each of which there stems a rigid strip that curves progressively backward, inward, downward, upward, and then forward to form a loop to receive the ends of the film spool when the latter is brought downward and backward from slightly forward and above to be inserted into position as described (fig. 5). This modification for receiving the rearward spool obviates the use of the two reducing studs previously employed. This decrease in the number of moving parts further adds to ease of operation.

It is desirable in some of the Rollex models, in addition to the above modifications, to rivet a thin metallic strip along each side of the bottom surface of the holder itself. These strips, of necessity, will vary slightly in length, breadth, and width, but their proper placement has the advantage of providing an exactly measured surface track for the guidance of the confined film strip as it progresses from the rear, or second and packed spool, to the forward receiving spool along the bottom aspect of the holder proper; furthermore, it also aids in preventing the metal rollers from becoming so axle-worn that they would rotate irregularly.

780 Park Avenue, New York.

REFRACTION CLINIC*

DISCUSSION BY ALBERT E.

SLOANE, M.D.†

Boston, Massachusetts

Case 1

A three-year-old girl, in whose left eye there had been about 10° of esotropia for distance and near, during the past eight months, was presented for examination.

EXAMINATION

Under atropine, she would accept O.D. +2.50D. sph.; O.S. -3.50D. sph. \approx -2.50D. cyl. ax. 180°.

What should be done in this case?

DISCUSSION

Can the squint be explained on the basis of excessive accommodation? We know that accommodation cannot occur in one eye without being expended in equal amount in the other. If a child fixates with the hyperopic eye, accommodation will be required, and it is not unlikely that this accommodation will cause an over-convergence effect or esotropia.

The fact that the hypermetropia is not high (+2.50D. sph.) and yet is capable of producing a squint, is explained by the fact that the vision in the left eye is relatively poor. Therefore, little fusion amplitude can be present to offset or neutralize the over-convergence response.

Thus, for all intents and purposes, the squint must be evaluated essentially in terms of the right eye.

TREATMENT

For immediate treatment it is well to consider this case as one of potential accommodative esotropia. In that case, we should fully correct the hyperopic error in the right eye to suppress all excessive accommodative effort. The left eye should be corrected for another reason: to improve the visual acuity as far as possible by sharpening the focus on the retina. However, we must be careful not to correct the myopia so fully that accommodation will become necessary, since at this stage we are attempting to suppress accommodative activity.

For this reason I would suggest correcting the astigmatic error, but well undercorrecting the spherical error O.S. and fully correcting O.D. Prescription: O.D. +2.50D. sph.; O.S. -1.50D. sph. \approx -2.50D. cyl. ax. 180°. Assuming that this would make the eyes straight, one could then attempt to improve vision in the left eye further by prescribing amblyopic exercises for the near vision: coloring pictures, and the like.

I do not believe we can hope for full binocular fixation with all refinements in view of the high difference in refraction (antimetropia.)

In the event the squint was not corrected by this method, one would probably resort to surgery. This should be postponed until it has been proved that:

* From the House Officers' Teaching Clinic, Massachusetts Eye and Ear Infirmary.

† Director of Department of Refraction.

1. Glasses do not help. 2. A resultant exotropia is not too likely to occur (because there will be more divergent effect as the head grows in size).

QUESTIONS

House Officer: Is it not true that many children of this age have latent hypermetropia (+2.50D.) without a squint?

Dr. Sloane: It is true that this amount of latent hypermetropia is a common finding, but in this child the binocular status of vision has already been handicapped by the high anisometropia, so that there is not an adequate desire to use both eyes together to hinder or restrict an excessive reaction on the part of convergence to accommodation.

H. O.: Would you not expect the myopic left eye to be an exotropic eye rather than in an esotropic position?

Dr. S: In this situation, there are two reasons that prompt an esotropic position for the left eye rather than a divergent one:

1. It is not the error of the eye itself that determines the position, but rather the demand on accommodation and the indirect demand on convergence. In this case, although the left eye is myopic, the demands on accommodation are made by the right eye, which is hyperopic, and the same amount of accommodation that goes to the right eye is also going to the left eye.
2. The orbit in a child under five tends to direct an eye that is not in use to a convergent deviation. Later the orbits tend to produce a divergent position in an unused eye. It is this transition from the convergent to a divergent direction that is frequently responsible for neutralizing a convergent squint, and it is to this sort of situation that one refers

when he says, "My son grew out of his cross-eyes."

H. O.: Would it not be feasible to occlude the right eye and build up vision in the left eye with a proper glass and then fully correct both eyes to emmetropia and train fusion at that time?

Dr. S: Theoretically one could equalize the retinal images with a correction, but we could not know until the child is older how much his visual acuity improved, and, in the meantime, we may be exposing him to a handicap through not using his better eye. For practical purposes it would be best to allow him to see well with his right eye, correct his strabismus if possible with glasses, and improve the amblyopic left eye by amblyopic exercises for near.

Case 2

A woman, aged 42 years, reported for examination, complaining of difficulty in seeing at near. She was wearing: O.D. +4.00D. sph.; O.S. +4.00D. sph. Uncorrected vision in each eye was 20/200. With a +4.50D. sph. for each eye, vision was 20/20. Add. +0.75D. sph. Wells I. With these lenses vertical and horizontal orthophoria was present.

DISCUSSION

Obviously the symptoms are referable to the combination of her requiring a greater plus value for distance and the onset of her presbyopia. The question that we are to decide is whether or not bifocals are indicated. People who have never worn bifocals before usually find it difficult to make the adjustment. Moreover, bifocals have certain objectionable features; such as, implying old age. (This is an important objection for many people.) Furthermore, at best, bifocals represent a compromise so that certain areas of the field have their clarity sacrificed in

the interest of the reading portion. On the other hand, there are definite advantages to bifocals, since they make immediately available a near and far correction without necessitating a change of glasses. Another factor favoring the prescription of bifocals here is that it is easier to get used to a weak segment ($+0.75D.$) than a stronger one.

I have found that bifocals are best tolerated when that situation is present where one cannot read at all with the distance glasses and yet can read through the reading segment. In other words, the patient has no choice as to which portion of the glass he must use in order to read. In cases where only a weak addition (like $+0.75D.$) is required for the near correction, the patient is usually able to read everything except fine print with the distance lenses. It is true that this ability to read with the distance lens cannot be maintained, nor is it always comfortable, but for purposes of transient vision it suffices. Thus this patient with her glasses made up as bifocals would be able to read through her distance glass, but be able to read still better through the bifocal segment. The difference between the distance and near segments therefore is not one of being *able* or *not being able* to see, but simply of seeing more clearly through the "add." Since for most purposes fine near vision is not requisite, the patient will not know whether to look through the segment, which is unnatural, or through the center of the glass, which is more natural. It is preferable to correct the vision for such eyes in the following ways:

Solution 1. Prescribe the full distance correction in single-vision lenses. These would serve for all ordinary work since distance vision will be good, and a person aged 40 years has about $3.50D.$ of accommodation to help for most near work.

In addition, give her the correction for near vision, also in a single-vision lens, for prolonged near work. I like to refer to this latter as a "library spectacle."

Solution 2. Order a distance glass in single-vision lenses and order *for near work* a bifocal. Wear the bifocal only for reading; this allows the person to get used to the bifocals gradually, subjecting him to none of their disadvantages. They later may be used entirely if the patient wishes.

3. Order bifocals where the occupation of the person is such that the most precise near vision should be available as well as the most precise far vision at the same time.

QUESTIONS

House Officer: What is the weakest bifocal strength (presbyopic add) that you would order?

Dr. Sloane: I usually start with $+1.50D.$ sph. add. I occasionally prescribe $+1.25$ add and only in unusual situations do I order less as a bifocal add.

H. O.: How does method 2 help solve the problem?

Dr. S.: In the first place, the patient is going to wear the bifocals only for reading. Here you require precise vision, and the person will easily be able to tell through which section of the glass she reads more comfortably. She will also have the opportunity gradually to accustom herself to other problems encountered in the use of bifocals. People of this age find it difficult to appreciate that their near vision should be different from what it was just a few years ago, and it is much easier to allow their reading glasses to bring home to them this fact than to talk them into wearing bifocals for constant use.

RECURRING JUVENILE VITREOUS HEMORRHAGE

MR. FRANK A. JULER said that the condition known in this country as Eales's disease was first described in 1880.

A summary of the literature and a description of the disease were given in 1932 by H. P. Hutchinson. Since that date there have been few references to it here, but on the Continent and in America it has received some attention.

Hutchinson (1932) concluded (1) that no constitutional disease is usually present, but often some measure of lowered vitality seems to exist, (2) that there is no satisfactory evidence that tuberculosis is a cause, (3) that the disease is probably due to a deficiency in some blood constituent or to the presence of some toxic product causing damage to the capillary endothelium with resulting diapedesis. He mentioned, too, a possible vitamin deficiency allied to scurvy, although no symptoms of scurvy except epistaxis have been noticed.

Lawson (1935), in a discussion on diseases of the blood, stated that Eales's disease was characterized by a marked increase in the coagulation time of the blood. Mr. Juler said that he had not been able to find any confirmation of this nor had his own observations shown that

this was true. As Hutchinson says, "Deficiency in calcium, prolonged bleeding time, and delayed coagulation seem to be ruled out in almost every case in which these points have been investigated."

R. T. Paton (1938) described five cases, and concluded that the condition was always traumatic, toxic, or infective.

Jeandelize and Drouet (1936) attributed the disease to an endocrine defect. They asserted that there was a condition of hyperpituitarism which might be either primary or secondary to hyper- or hypothyroidism or to a dysfunction of the adrenals or gonads. Its presence was shown by the detection in the urine of a melanosome-dispersing factor. The only other evidence which they gave was (1) a narrowing of the visual fields, chiefly bitemporal, amounting to 10 or 20 degrees, and (2) hypertension of the retinal arteries.

Recent work by Noble and others (1938) on the posterior lobe of the pituitary has shown that injection of its extract produced pressor effects and hyperglycemia, sometimes with achlorhydria and hyperchromic anemia, while the urine of the experimental animals contained substances producing pressor and anti-diuretic effects; from a test on the frog a melanosome-dispersing action is obtained. Idris Jones (1938) described a case in which these findings were detected clinically and diagnosed as due to an over-activity of the posterior lobe of the pituitary gland. His patient was a man, 26 years old, and the disability lasted only a few months. There was no vitreous hemorrhage.

Dax (1938) reported the presence of a melanosome-dispersing substance in the blood and urine of eight adult mentally

defective patients with retinitis pigmentosa. Idris Jones said that he would hesitate to say that this substance is pathognomonic of hyperpituitarism, but should there be other evidence of excessive pituitary action, then it could be used as a confirmation.

McArevey and Somerville-Large (1939) reported two cases of Eales's disease in which there was a low excretion of vitamin C in the urine; neither patient had suffered a relapse since that diet was augmented. The period of freedom from recurrence was, however, not stated. Several observers, including Hutchinson (1932) have suggested that some deficiency condition may be present in this disease, and the above observations invite confirmation.

Harris (1940, 1942) recently found that school children showed a low level of vitamin C at the end of the winter, and that the present average was lower than in a pre-war period.

The symptomatology of severe vitamin-C defect was described by Crandon (1940).

These researches indicated that ascorbic acid is stored in the body, and that a high blood and urine content was found only after saturation had been reached. The determination of the body content, therefore, requires more than a simple estimation of the amount of vitamin C in the urine or plasma.

In the cases reported by Mr. Juler no investigations were made on this possibility, though from clinical experience during two years of war it did not appear that Eales's disease was on the increase, as one would expect if an ascorbic-acid deficiency of a mild type were in some way a factor.

In "Modern trends in ophthalmology" (Ridley and Sorsby, 1940) Redslob emphasizes the presence of an actual periphlebitis of a tuberculous nature, an ex-

planation which was strongly supported by Axenfeld, Stock, and others. He refers also to Marchesani's theory that Eales's disease is a manifestation of Buerger's disease (thrombo-angiitis obliterans). Marchesani's patients had circulatory disturbances varying from a simple sensation of cold to a spontaneous gangrene of the extremities. Kokott (1935) investigated five cases; no evidence of Buerger's disease was discovered, nor had any symptoms of this kind been detected in the cases observed by Mr. Juler.

Duke-Elder (1940) stated that Eales's disease was the commonest type of tuberculous periphlebitis, but that it may also occur as the result of septic foci, Buerger's disease, helminthiasis, delay in blood coagulation time, endocrine defects, and calcium deficiency. "The main feature in most cases is the normality of the general metabolism."

With regard to tuberculosis, the absence of clinical evidence in most cases is definite, but cases in which there were active pulmonary lesions were reported by Bonnet, and others (1936), and Kokott (1935), while Somerville-Large (McArevey and Large, 1939) saw three cases of Eales's disease with old-standing tuberculous lesions in the hilar glands. Microscopic examination was not possible, but Fleischer in an excised eye found a single focus of inflammation in the ciliary body, hemorrhages along the retinal veins and on the retinal surface, with tuberculous nodules in the venous walls. Gilbert (1935) found tubercle bacilli in a nodule in the wall of a vein; the eye had been excised for secondary glaucoma in a young man suffering from severe pulmonary tuberculosis: it was not a typical case of Eales's disease but it proved that tuberculous periphlebitis does occur.

From Mr. Juler's personal observations the appearances in the fundus are in the

most cases obscured by the grossness and density of the vitreous opacity, but in some of the less-severe attacks it is possible to see the apparent origin of the hemorrhage and in others a residue can be seen when the hemorrhage has cleared.

Mr. Juler presented eight cases in which there was a striking absence of any tangible general disease, except in one in which there was a chronic osteomyelitis of the great trochanter.

In no case was any evidence of tuberculosis obtained. This was in contrast to the findings in a recent study of chronic iridocyclitis (Brooks and others, 1940) in which clinical or radiologic evidence of tuberculosis elsewhere in the body was present in 25 of the 40 patients. Another negative feature was the absence of any general tendency to phlebitis or venous thrombosis.

On the contrary, all the patients except the one with bone disease were physically and mentally in good health. Possible sources of sepsis, such as tooth or tonsillar pockets, were not found during routine examination. Investigations concerning a possible hyperpituitarism and vitamin deficiency had not been carried out. In only one case was the blood pressure above the normal for the age of the patient; there was no increase in the color density detected in the routine blood counts, such as might have been found if a posterior-lobe hyperfunction had been present.

In three of the series of eight cases, iridocyclitis was present and foci of choroiditis were found in one other. The iridocyclitis was nonrecurring and for the most part of a mild type.

The ophthalmoscopic study of this series suggested that in many the hemorrhage occurred from one or more branches of a retinal vein, and that recurrence may have derived from the same site, leaving little residue beyond a twist-

ing and kinking of the vessel, sometimes associated with a localized traction forward of the retina. It has been recorded by several observers that occasionally no change can be found in the fundus after the vitreous has cleared. This has led to the suggestion that a diapedesis rather than a loss of continuity supplies the actual hemorrhage.

Although some eyes are undoubtedly badly damaged, the majority retain good vision. In many of the cases reported in the literature and in those which form the basis of this report, hemorrhages do not recur after a varying period. In Hutchinson's cases (1932) this was from six months to four years.

Of the cases reported by Mr. Juler, only one had been watched a sufficient length of time to be certain that there was no further danger. In that patient, seven years had elapsed since the last hemorrhage, which was one of five over a period of three years. In another, the right eye had many relapses over a period of five years, finishing with an iritis, and has been free for 13 months. His left eye had suffered several hemorrhages during a period of 11 months and has been free for 8 months. Two others have been free for eight months, one after five hemorrhages in $5\frac{1}{2}$ years, a second after four hemorrhages in $1\frac{1}{2}$ years. The intervals between the attacks vary from a few weeks to three years, but the average is approximately nine months.

One may conclude that in the great majority of attacks the visual acuity is only temporarily impaired, but that there is always danger of a serious attack during the period of susceptibility. Even after these severe attacks the eyes have a fair chance of good recovery.

Treatment consists of complete bed rest for a few days at the onset, in order to help clotting at the site of the rupture.

None of the coagulant drugs appears

to be of any value. Intravenous injections of calcium gluconate and chloride in one of Mr. Juler's cases were not followed by any shortening of the coagulation time. In the same way hemoplastin and vitamin K cannot be expected to be of value. The hemorrhage is not due to any deficiency in the coagulation power of the blood, it must be due to the local lesion in the vessel wall.

The general well-being of the patient is most important. The ideal is a sheltered life, with plenty of sleep, good food, and gentle exercise. In the background is the prevention of recurrences. The periphlebitis or perivasculitis in the area concerned is usually of a mildly infective nature, but any definite focus may require radical treatment. Apart from this, it may be well to attack the infection by general empirical means, such as protein-shock therapy by means of the intravenous injection of T.A.B. vaccine. Such treatment might stop further infection, although it need not be expected to strengthen the resistance of weakened walls.

The other possibility of stopping recurrences is by diathermy. In his Bowman lecture, Weve (1939) pointed out many uses for the high-frequency treatment, and in certain cases of Eales's disease it might be suitable to application. The patients in some of Mr. Juler's cases appeared to have bled from the same vessel on succeeding occasions. It would seem justifiable to produce a reaction over the area affected so as to include the "phlebitis sector" in the ensuing scar. A surface application would suffice, and if it were within 14 mm. of the limbus the ensuing defect in the visual field should not be large.

The treatment of vitreous hemorrhage is uncertain if the hemorrhage is very great. The clearing does not seem to depend on age, for, Mr. Juler states, he has

seen an improvement of vision from the perception of hand movements to 6/18 in three weeks' time in a 67-year-old woman who had a mild degree of hypertension.

Organization of vitreous hemorrhage by endothelial proliferation frequently does occur, and the pathology of formation of blood cysts in the vitreous was recently demonstrated by Wolff before the Ophthalmological Society of the United Kingdom. Once these fibrous walls and bands have developed, they will remain, and indeed detachment of the retina is known occasionally to result.

In the present series vitreous aspiration has been used on one occasion only, and with a resulting iritis and detachment of the retina; however, in the treatment of traumatic vitreous hemorrhage it is certainly useful. With a preliminary surface diathermy at the site of the puncture, the danger of hemorrhage is reduced, while detachment should not occur if the puncture is made at the "site of election"—namely, the pars plana—at a point 6.5 to 7.5 mm. from the limbus.

With such precautions, in the treatment of vitreous hemorrhage from pathologic causes there should also be some improvement.

As an alternative to aspiration Weve (1939) has suggested diathermic puncture of the sclera following a local surface coagulation; if necessary, a certain amount of fluid can be sucked or pressed out. It is indicated after traumatic or operative hemorrhage, and in vitreous opacities due to chronic inflammation.

Other methods of treatment for the clearing of severe hemorrhage are: (1) short-wave diathermy, (2) subconjunctival or retro-orbital injection of hypertonic saline. The latter is probably of no value, whatever, except for psychologic reasons.

DR. ISADORE GIVNER, *presiding*

EXHIBIT ON NEURO-OPHTHALMOLOGY

DR. DONALD J. LYLE presented an exhibit that illustrated graphically the effect of brain diseases on the eyes. The diseases studied included neoplasms, diseases of the blood vessels, and various types of inflammations.

RETINAL CHRONAXIA IN HEALTH

DR. BENJAMIN FRIEDMAN presented a paper on this subject which will be published in this Journal.

RELATIONSHIP OF THE CEREBROSPINAL-FLUID SYSTEM TO OPHTHALMOLOGY

DR. DONALD J. LYLE outlined the embryologic development of the brain, in which the neural tube undergoes vesiculation in the parts of greatest growth. These vesicles, which are called ventricles, are joined, and through them the cerebrospinal fluid passes, finally to reach and bathe the cerebral surface. The ventricles are molded by central visual paths and other ophthalmologic structures which are frequently implicated in lesions of the cerebrospinal-fluid system.

Hydrocephalus, caused by an excess of production of cerebrospinal fluid, a defect in absorption, or a blockage of its flow by tumors, inflammations, blood clots, or other causes, frequently produces choked discs, visual-field changes, and involvement of the sensory and motor nerves to the eyes and adjacent structures.

Lesions in the temporal and occipital horns of the lateral ventricles frequently produce visual-field changes by implicating the optic radiations. Lesions involving the third ventricle frequently affect the optic tract and chiasm at the anterior end,

which affection may be due to a blockage of the aqueduct of Sylvius at the posterior end.

The nuclei of the nerves to the eye muscles are subject to lesions in the aqueduct of Sylvius and the fourth ventricle as they lie in the ventricle wall.

The emerging nerves in their course through the subarachnoid spaces from the brain or brain stem to the orbits may also be affected by inflammation and pressure from tumors, blood clots, and other causes.

The cerebrospinal-fluid system in its relationship to neuro-ophthalmology is of paramount importance, and clinical ophthalmologists should have a working knowledge of this subject.

Discussion. Dr. Alfred Kestenbaum stated that the dura is partly divided into two layers, a parietal and a visceral one. Three intermeningeal spaces may be thus differentiated: (1) the subarachnoid space between the pia and the arachnoidea; (2) the subdural space between the arachnoidea and the visceral dura; (3) the "epidural" space between the visceral and the parietal layer of the dura. In the spinal canal there are, as a matter of fact, these three well-separated spaces.

In the skull the subdural space is normally only a virtual one. The subarachnoid space is known as the cisternae—as, for example, the cisterna of the optic chiasm—and is filled with cerebrospinal fluid. The intracranial part of the optic nerve, the chiasma, and the optic tracts run through the subarachnoid space as do all large basal arteries, except the internal carotids. In contrast to the arteries, the entire venous system—the sinus at the convexity as well as the system of the cavernous sinuses—lies in the "epidural" space. The cavernous-sinus system and the hypophysis are separated by the visceral dura from the optic chiasma. This has the following significance: the

so-called intracranial pressure is present only in the subarachnoid space and within the brain. The venous-sinus system, however, situated in the epidural space, is protected by the dense dura; the pressure on the venous vessels is therefore more independent of the intracranial pressure (Sabanski). Otherwise in instances of highly increased intracranial pressure the blood from the orbit could not enter the skull at all. Therefore Sabanski, who found the diastolic pressure in the retinal veins (measured by Bailliar's ophthalmodynamometry) to be almost equal to the intracranial pressure, had to explain this fact by the relation of the vein to the subarachnoid space in the optic nerve, and not by the pressure relations in the cavernous-sinus system.

The difference in the pressure-conditions between the "epidural" space, in which the hypophysis is situated, and the subarachnoid space, which continues into the sheaths of the optic nerve, has to be considered in the explanation of the fact that tumors of the hypophysis almost never cause a choked disc.

The subarachnoid space and the subdural space, but not the "epidural" one, continue into the optic nerve up to the lamina cribrosa of the disc. Therefore the subarachnoid space of the optic nerve is in open communication with the subarachnoid space of the skull, as Tsuboi has emphasized. The pressure in the subarachnoid space of the optic nerve is therefore almost identical with the intracranial pressure and with the pressure found on lumbar puncture (in the recumbent position). The lamina cribrosa virtually separates two pressure spaces: the intracranial (better subarachnoid) space and the intraocular space. If the lamina cribrosa were a very elastic membrane, its position would be a direct expression of the relation between intracranial and intraocular pressure. On increasing the

former or decreasing the latter it should advance; on increasing the latter it should be bent backward. The small degree of elasticity of the lamina hinders such an extensive bending, but this point deserves attention in the explanation of many facts: the advancement of the lamina in papilledema, which Duke-Elder emphasizes; the occurrence of "papilledema" after perforation of the eyeball; the sometimes observed decrease or even disappearance of an excavation in recent cases of glaucoma after decrease of the tension; the dependence of the pressure of the retinal veins on the intracranial pressure (Baurman); the mechanism in primary optic atrophy according to Sabanski and Lauber.

In conclusion Dr. Kestenbaum stressed the facts that (1) the orbital veins open into the "epidural" space, which is relatively independent of the intracranial pressure; (2) the hypophysis lies in a "pressure-space" other than that of the optic pathways; (3) the lamina cribrosa of the disc forms a thin separating wall between two pressure-spaces, the intraocular space and the subarachnoid space, and therefore between the intraocular pressure and the intracranial pressure.

Dr. Ralph I. Lloyd stated that Dr. Lyle had shown the importance of the ventricular system in the diagnosis of brain conditions. Several theories have been offered to explain choked discs but the most reasonable, it seems, is Oppenheim's. He claims that the fluid escape from the ventricles into the submeningeal spaces is blocked by pressure upon the narrowest part, the iter. Distension of the third ventricle ensues, producing pressure upon the optic chiasm immediately below. This pressure blocks the return flow of lymph along the perineural spaces of the optic nerves, which, in turn, inhibits the flow of venous blood in the optic nerve anterior to the bony canal where the central artery

and vein enter and depart. Lantern slides were shown in support of this theory. The first showed a tumor of the cerebello-pontine angle, tumor in place, and the second, the effects of the pressure it exerts upon the cerebellum, resulting in marked atrophy of the lobe of the affected side. The next two slides showed the dilated third ventricle in this case and the normal ventricle. The next two slides showed the petrous portion of the temporal bone from this case with the atrophy of the bone about the auditory-nerve entrance and also a normal petrous bone. Dr. Lloyd pointed out that in brain tumors with choked disc there is no great quantity of fluid escape when the meningeal membranes are opened. The pent-up fluid is in the ventricles, and a trocar introduced preferably into the extremity of the posterior horn of the lateral ventricle allows this to escape and is the usual practice in operations to lower the pressure.

THE PUPILLARY REFLEX TO DARKNESS

DR. OTTO LOWENSTEIN stated that, until 1939, it had generally been supposed that the same mechanism was involved in the pupillary reflex to light as in the reflex to darkness; that is, the response to a short interval of darkness of a pupil that has been adapted to light. In that year, Lowenstein and Franceschetti showed for the first time that the two reflexes are independent of one another.

The reflex to darkness is elicited clinically by two flashlights, so arranged that the light from each flashlight reaches only one eye. After a short period of adaptation to these lights, one of them is extinguished for about a second. This "darkness stimulus" produces a reaction consisting of three phases: a primary phase of dilation, a contraction phase which begins after the darkness stimulus comes to an end, and a third phase of redilation

in which the normal pupil regains its original width. The reaction takes place both directly and consensually. As compared to the light reflex of the same individual, the dimensions of the reflex to darkness are considerably less. In a person, for example, whose contraction to light amounts to three millimeters, the dilation to darkness amounts to only two-thirds of a millimeter. During the darkness period, the reaction to darkness can be observed only clinically in the consensually reacting eye; pupillographically, the reaction of both eyes can be recorded during the entire period of reaction.

In cats, the reaction to darkness is as great as the reaction to light. The redilation phase, however, is not found; this is also true of monkeys, rabbits, and pigeons. It is of interest that in pathologic conditions in man, the phase of redilation disappears more readily than do the other phases.

In pathologic cases, any phase of the darkness reflex may be absent, independently of the other phases, and independently, too, of the reaction to light. For example, one might find cases in which good contraction is manifested in the light reaction but the redilation is inhibited, whereas the reflex to darkness shows a good dilation phase, and vice versa.

A case is shown in which, after the surgical removal of a pinealoma, the light reflex was absent; the reflex to darkness, however, was exaggerated in its first phase (dilation) although the third phase (redilation) was absent. This shows dissociation of the nervous pathways of pupillary control for the reaction to light and to darkness. We are not able to state the exact location of the lesion, for no anatomic evidence is present, but there must exist at least one point in the brain where the pathways of the two reflexes are not identical.

Discussion. Dr. Otto Marburg gave a review of the pathways for pupillary reflexes. He emphasized that the anterior median nucleus proper only (not the vertical limb of Edinger-Westphal's nucleus) is the motor nucleus for the light reflex. Edinger-Westphal's nucleus is a sympathetic nucleus, and as new investigations with Mettler on cyclopiian brain have shown, no fibers from this nucleus enter into the oculomotor nerve. The fibers of this nucleus cross the side and enter into the tegmentum, thence running into the spinal cord. As for the dark reflex, the exact investigations of Lowenstein are convincing. In the retina there are solely cones and rods (that is, color and light receptors); there may be a receptor also for darkness. But in the receptor layer of the calcarine area there are only two different kinds of cells: light and color receptors as revealed by investigations on monkeys that see by night only. (Vogt, Henschen's studies on *Perodicticus Potto*.) It may be that there is a similar mechanism as for sleep (two different centers for falling asleep and for awakening), but that remains to be proved.

Dr. Mark J. Schoenberg presented a series of pupillographic curves from cases of glaucoma. These curves brought out a number of anomalies some of which were: (1) a slight disturbance of the first phase and a marked disturbance of the second phase, (2) the second phase is very similar to that found in normal monkeys.

Dr. Isadore Givner pointed out the value of the reaction to darkness in differentiating Adie's phenomena from the Argyll Robertson pupil. There are two types of darkness reflex in Adie's disease. The first shows the dilation to darkness but no subsequent contraction and redilation. The consensual reflex to this reaction when the affected eye is stimulated is normal. When, however, the nearer nor-

mal eye is stimulated the dilation to darkness in the affected eye is also diminished; there is, as well, an absence of the contraction and redilation following. The second type shows no reaction at all in the affected eye and a markedly reduced darkness dilation effect in the consensually acting eye. When, however, the nearer normal eye is studied, there is a diminution in dilation to darkness in this eye and an absence of reaction in the affected eye. Dr. Lowenstein believes that actually both eyes are affected in Adie's disease though one eye is outstandingly so. In the Argyll Robertson pupil there is no reaction to darkness either directly or consensually, whether or not either eye is stimulated by darkness.

OCULAR MANIFESTATIONS OF INTRACRANIAL PATHOLOGY

DR. E. A. SPIEGEL discussed the local-diagnostic significance of visual disturbances, eye-muscle palsies, and of nystagmus caused by intracranial pathology. He found, with N. Scala, that there is a second type of central vertical nystagmus, besides that seen in lesions of the vestibular nuclei. This second type of vertical nystagmus appears in the acute stages of cerebellar lesions, particularly in certain positions of the head, and is considered to be the result of a release of vestibulo-ocular reflex arcs from cerebellar inhibition. This result may shed some light upon the controversial question whether nystagmus occurs in cerebellar lesions. There seems to exist general agreement that cerebellar tumors or abscesses affecting the vestibular nuclei by pressure or edema may induce nystagmus. It is, however, a moot question whether nonspace-taking lesions that are restricted to the cerebellum may cause the appearance of nystagmus. Some authors admit this possibility, others deny it. The present series of experiments

seems to confirm the former opinion, since we observed nystagmus in cerebellar lesions with the vestibular nuclei and their extracerebellar pathways histologically intact. These experiments further showed that cerebellar nystagmus may escape observation if one examines in the normal position of the head only, so that the examination for nystagmus in cerebellar lesions should routinely include the observation of the eyeballs in the normal as well as in abnormal positions of the head.

Discussion. Dr. Alfred Kestenbaum stated that two kinds of vertical jerky nystagmus are generally known. In one group a lesion of the region of the collicular plate is found anatomically, in the other group a lesion of the superior part of Deiter's nucleus. The first kind may be explained as a gaze-nystagmus—a disturbance of upward gaze, as paralysis of

gaze may also occur in a lesion of the collicular region; the second kind may be explained as a central vestibular nystagmus. The interesting results of the experiments of Spiegel would show the existence of a third kind of vertical jerky nystagmus as a consequence of a cerebellar lesion, if such a nystagmus were observed clinically, too.

Dr. Frank C. Keil stressed the importance to the ophthalmologist of Dr. Spiegel's contributions pertaining to the central connections and pathways of the ocular nerves. He cited briefly a few case reports of lesions of the ocular nerves of unverified etiology and stated that it was not always possible to follow the different phases of ocular palsies, as the true cause of a lesion may become manifest only months or years later.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Lawrence T. Post, 640 South Kingshighway, Saint Louis 10, Missouri*; Society Proceedings to *Dr. Donald J. Lyle, 904 Carew Tower, Cincinnati 2, Ohio*. Manuscripts should be typed in double space, with wide margins.

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver, Colorado*.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE OPHTHALMOLOGIST'S ROLE IN THE PROGRAM FOR THE PARTIALLY SEEING CHILD

The book by Winifred Hathaway on "Education and health of the partially seeing child" is reviewed in this issue of the Journal. The program is in its infancy, not having been initiated in the United States until 1913. Only a small part of the estimated 50,000 eligible children have as yet been enrolled in sight-saving classes. There has been a diversity of opinion as regards the amount of vision desirable for enrollment in this program, the upper limit of acuity in some

states being 20/70 whereas in others it is as low as 20/200 in the better eye with suitable glasses. Only the phases of this subject referred to in the title of this editorial are here considered.

The ophthalmologist enters into the picture in two different roles. He is primarily the most important factor in the selection of pupils for these classes. Secondly, his must be the continued supervision of the patients if they are admitted to the classes. Superficially the task of selection and bringing about the inclusion of the desired children into sight-remedial classes seems simple. Actually, however, this is not the case, there being an inher-

ent disinclination on the part of the parents to have the child segregated in any manner from his fellows, to say nothing of the mechanical difficulties of transportation and added expense. From the doctor's standpoint it is important that he shall be convinced of the value of these sight-conservation classes or he will make a poor salesman.

The first screening must usually be done in the schools. This requires the education of school personnel or of the school physician in the matters of vision taking and of the significance of sight-conservation classes. After defective vision is found the child is usually referred to a refractionist. In some places this must be a physician, but in others optometrists are acceptable to the school boards. Whatever the instructions, parents often take their children to optometrists, so that they also must be aware of the sight-conservation program and of its merits.

It is advisable to be prepared to combat parental objections, which are almost sure to arise, by elimination of the probable points at issue in advance. For example, the child should not be segregated completely from his fellows, but should recite as much as possible with his own class and be in the special classroom only for those studies to which conservation of eyesight especially pertains. For athletics and other nonsight-taxing pursuits these children should be with their classmates, since it is important that they do not get the point of view that they are handicapped and segregated. In this regard it is vital that children with defects other than ophthalmic be not included in these groups. For example, it is never wise to send the mentally defective child to such a class merely to get him out of the way because he is a nuisance in the normal group.

Transportation is a real problem. In order to accompany the younger child it is sometimes possible to have an older

child transferred to a school in which there is a sight-saving class for the younger child with defective vision. In some cities school busses are available. The expense, if it cannot be borne by the family, should be provided for by the city.

Everything should be done to take away any possible stigma connected with enrollment in these classes. The ophthalmologist should know of the program in his own community and be interested in seeing that it is being conducted in as intelligent and efficient a manner as possible.

Regarding the question of what children should be enrolled in the classes, it is relatively simple to ascertain the best vision with glasses. But there is a divergence of opinion regarding such matters as myopia. Many doctors believe that the child with marked myopia should be in a conservation-of-sight class, irrespective of whether the vision is below that of the allowable limit in his community or not; whereas others do not share these views as to the ill effect of use of the myopic eye. Such points as these will have to be decided in the individual case by the examining physician. An ophthalmologist who is wholeheartedly in favor of the program (and it is incredible that any well-informed doctor should be otherwise) will be more successful in persuading the parents that the child in question should have the benefit of these classes. Usually, the parent is entirely unaware of the sight-saving classes and has to be convinced of their value. The first reaction is almost always one of opposition to them, and this is especially true if the child is doing well in his school work. It is generally only when the grades begin to fall and the child in becoming a misfit that the reluctance of the parents for such classes is overcome. It is very often difficult to convince parents in the former case of the value of the class in protecting the child's vision for the future.

The physician's task is greatly helped

if a certain amount of favorable propaganda is carried on by the school board. An attractive method of doing this is the portrayal of the classes and their work in the rotogravure section of Sunday papers. In most cities there are parent-teacher associations. Lectures to them on this subject would be very helpful in popularizing the effort. The objections are usually from ignorance rather than from any other factor.

The care of the child when entered into these classes is no different from that of a partially seeing child under any circumstances. The only feature that need be stressed is the necessity of systematic ocular examinations, as the condition of the child's eyes may change relatively rapidly. Frequent reexaminations in the schools are necessary also. The entire program is a very worthy one and will be greatly helped by the active participation of the ophthalmologist.

Lawrence T. Post.

GLAUCOMA AND NASAL SINUSES

Concerning the mechanism of certain cases to which we attach the diagnosis of "secondary glaucoma" we know a little. With regard to the causation and development, particularly in the earlier stages, of the disorder to which we apply the title "simple glaucoma" we know almost nothing.

The expression "simple glaucoma" implies more or less that we are dealing with an insidious type of glaucoma for which we are unable to establish a cause.

It would be encouraging to suppose that we could assign a clearly defined and well understood cause to this disease. Proof of such a discovery would constitute one of the greatest modern advances in the science of medicine. This would be particularly true if the cause discovered were of

such a nature that the cause could be corrected or remedied, and that such remedial action would either prevent or cure simple glaucoma.

It is interesting to reflect that as soon as (if ever) we find such a cause, or perhaps a related group of causes, we shall have to discontinue the use of the term "simple glaucoma" and must regard every case of glaucoma as secondary. Simple glaucoma is among a number of conditions (as for example essential vascular hypertension) whose titles are confessions of ignorance.

Many attempts have been made to trace a connection between simple glaucoma and various types of focal infection. The incriminated sources have included the teeth, the tonsils, the nasal sinuses, the gall bladder, the genito-urinary tract, and the large intestine. Infection existing in any one of these areas has been more or less frequently blamed upon another of the group, an example being the attribution of sinus disease to dental granulomatata.

Last year, before the American Academy of Ophthalmology and Otolaryngology, Berens and Nilson (Transactions American Academy of Ophthalmology and Otolaryngology, 48th meeting, 1944, January-February, page 121) discussed evidence which seemed to them to point to the nasal accessory sinuses, among other foci of infection, as playing a prominent part in the etiology of so-called chronic simple glaucoma. These authors urged more particularly that, if it could be shown that a large proportion of cases of simple glaucoma occurring in one eye only, or especially marked on one side, coexisted with nasal-sinus disease on the same side, this fact would constitute a strong ground for assuming a causal connection between the two conditions.

It is stated that of fifty-three cases included in the study, in nineteen the glaucomatous condition was more marked in

the left eye and the evidence of nasal involvement was either confined to the left side or more pronounced on that side. In eighteen cases there was suggested a similar relationship on the right side.

Especially in view of recent researches with regard to the viruses, it seems not unreasonable to suppose that many inhabitants of the so-called temperate zone who have been severely or frequently attacked by influenza or the common cold are likely to nurture a chronic and perhaps lifelong, although usually inactive, infection of the nasal sinuses. Moreover, an extremely mild and hardly recognizable infection of one kind or another has often been shown to be capable of just as much secondary mischief as an active and more clearly demonstrable infection.

Thus the field of investigation upon which Berens and Nilson have set out lends itself much more readily to somewhat vague conjecture than to positive demonstration. The difficulties with which the subject bristles are vigorously illustrated in Woods's discussion of the paper of Berens and Nilson. The authors of the paper themselves admit that "the difficulties of proving a definite relationship between the simultaneous occurrence of sinus disease and chronic simple glaucoma from the experimental or even the clinical standpoint seemed to be unsurmountable."

Judgment concerning the relationship between glaucoma and any focal infection is rendered difficult by the fact that the essential degenerative changes more directly responsible for the glaucoma are likely to be permanently established before the causative factor can be investigated, recognized, or removed. A further difficulty in establishing the chain of evidence is the fact that the glaucoma, once established, must be persistently treated with miotics or combated with a surgical operation.

There is a definite possibility that the

only causal connection between what we call simple glaucoma, on the one hand, and chronic sinusitis or other focal infection, on the other hand, is through their common relationship to a degenerative process in the reticulo-endothelial system. Such a degenerative tendency might owe its existence to one or more acute or chronic infections, or might itself have created a reduced power of resistance in the patient. From this point of view, the problem of preventing simple glaucoma may be tantamount to the difficult task of finding a means for the cure or prevention of essential degenerative changes in the body as a whole, and particularly in its endothelial circulatory structures, including the canal of Schlemm.

W. H. Crisp.

BOOK NOTICES

EDUCATION AND HEALTH OF THE PARTIALLY SEEING CHILD. By Winifred Hathaway. Clothbound, 182 pages, 26 plates, 9 figures. Published for the National Society for the Prevention of Blindness, Inc., New York, Columbia University Press, 1943. Price \$2.50.

This is an excellent book on this subject. It covers most of the important aspects and is quite readable. For most ophthalmologists it will contain information that will be valuable and is not readily available to them.

The volume is divided into four parts. I. Ten pages about the historical background. II. This, the longest chapter, is on administrative responsibilities. III. Educational responsibilities. IV. Community social service responsibilities. Lastly, appendixes, a comprehensive series of chapters on diverse subjects closely related to the main thesis of the book; such as, Facts about the eye and Eye hy-

giene; Vision testing, a screening process; Outline for checking lighting facilities and equipment for eye work in the class room. A good bibliography and index complete the work.

As a guide for establishing sight-saving classes this book will serve as a satisfactory outline. The author indicates the different types of classes that are possible in order to meet the varying requirements of diverse communities. Details such as equipment and costs are given. The necessity of coöperation of the ophthalmologists for the success of the program is pointed out.

Lawrence T. Post.

REMEDIAL TECHNIQUES IN BASIC SCHOOL SUBJECTS. By Grace M. Fernald. Clothbound, 349 pages, with 49 illustrations. New York, McGraw-Hill Book Company, Inc., 1943. Price \$2.75.

This book by Dr. Fernald, associate professor of psychology at the University of California at Los Angeles, has for its objective primarily the report of certain psychologic experiments in the development of skills in the basic school subjects of reading, writing, spelling, and arithmetic. The outstanding contribution is the presentation of the author's methods for overcoming "word-blindness." Her phenomenal success in this field has been well recognized for many years, and doctors and educators alike will welcome this long-awaited compendium of her methods and results.

There are hundreds of thousands of nonreaders and partial reading-disability problems in the elementary schools of this country. The children affected with this condition are usually possessed of normal intelligence and often superior mechanical skill, and should become our finest citizens. Instead they develop seri-

ous negative emotional reactions to school because of constant failure in school work, and finally a definitely antisocial attitude.

The problem becomes of special import at this time, as the majority of cases are found in males possessing the very characteristics needed in war activities, but who, upon application for admission to the Army, are excluded or classified as illiterates. A survey of Dr. Fernald's cases, presented as part VI of this book, reveals that many adults coming to her at 17 and 18 years of age responded almost miraculously to her method of teaching. Her success should be a challenge to educators for early recognition of cases meriting application of remedial technique, and a plea for more extensive training of teachers of remedial reading for children and adults alike.

Every ophthalmologist should read this report, for any child who becomes a reading problem is likely to be referred to an ophthalmologist in hopes of finding some visual defect that may account for inability to learn to read. The ophthalmologist must not feel that his responsibility ends with a declaration that the child's eyes are not a factor in the reading difficulty. He should become sufficiently well acquainted with Dr. Fernald's work to advise the child's parents and teachers as to the seriousness of their negligence if they do not insist on remedial reading for the child, and to instill into the child and the parents absolute confidence that the handicap can be cured.

Instructive to ophthalmologists is Dr. Fernald's discussion of eye conditions that may affect reading skills, and of eye movements in reading. Her conclusions become authoritative by virtue of her clear thinking and her serious consideration in the cases she has studied of any relation between eye conditions and learning. She has found many individuals with

monocular vision, nystagmus, involuntary spastic head-jerking, and so forth, who read with a high degree of speed and comprehension provided the mechanism of the eye is such as to give a clear retinal image.

Dr. Fernald's supreme skill in simplifying material heretofore presented in a complicated and complex manner makes this treatise easily comprehensible and enjoyable reading, and thereby of incalculable value.

For instance, her description of her method of teaching reading is so clearly and concisely reviewed as to be apprehended by every interested teacher and the average parent.

Dr. Fernald says: "All authorities agree that the causes of reading disability are numerous and vary from case to case. Certainly our results with both children and adults suggest that no one specific disorder is responsible for the seeming inability of some individuals to read. Such conditions as poor vision or hearing, illness, or other physical disabilities, poor homes, poor schools or other unfavorable environmental conditions, extreme emotional instability, mental deficiency, or other mental maladjustments have long been recognized as responsible for reading failures. In most of these cases, individual work and correction of the faulty condition result in normal learning. Many of these cases can be treated successfully in a schoolroom by the use of accepted techniques, provided the child is given special attention in a small group with a strong teacher. After we have eliminated all cases due to the foregoing conditions, we still have a residue made up of individuals who fail to learn under the most careful instruction by methods that are successful with the average child."

She then discusses the techniques found successful in treating such cases.

The general plan of procedure in teaching these children to read is, first, to tell the child that many bright people have had the same difficulty he has and have learned to read by a new method which he may try. He selects any word he wants to learn. It is written for him with crayola on paper in plain blackboard-size script or print. The child traces the word with finger contact. This kinesthetic approach is the key to the situation. Learning is much more rapid when the word is traced with finger contact than when a pencil is used. The child says each part of the word as he traces it, repeating the tracing process until he can write the word without looking at the copy. As soon as the child realizes he can learn to write words, he starts "story writing." In extreme cases the child must learn by the tracing method every word to be used in his story. He asks for any words he wishes to use, learns them, and writes his story. After a story has been written it is typed for the child and he reads it in print. The child files away in his alphabetical word file the words he has learned and used.

After a variable period of tracing the child develops ability to learn new words easily without tracing. His stories become longer and more complicated. They are always typed for him and read by him. Soon he can learn from the printed word by looking at it and saying it before writing it. He recognizes difficult words after once writing them. He begins to want to read books. He is told words he does not know and writes them to learn them. Soon he makes out new words from their resemblance to words he already knows. Then he is eager to read, and delights in his ability to recognize new words without being told what they are.

Dr. Fernald's remedial technique for Mirror Writing is simply to start the child at the left edge of the page, so that the only direction in which his hand can

move with the pencil on the paper is left to right. If the child is left-handed she says, "You write with your left hand. Always start at the edge of the page on the same side as your hand." If the child is right-handed she says, "You are right-handed. Always start on the edge of the page on the opposite side from your hand." The child soon becomes accustomed to placing his pencil at the left edge of the page. He has no difficulty in reversing his inverted writing after establishing the initial position, and the mirror writing disappears within a few days.

Dr. Fernald has been equally ingenious in her analysis of difficulties in spelling and mathematics, and in devising ways of overcoming these difficulties. We cannot expect every teacher, even heeding scrupulously Dr. Fernald's suggestions and admonitions, to be as skillful as Dr. Fernald in handling these problems, but an attempt at understanding and applying her remedial techniques should be demanded of every individual responsible for the training of children in basic school subjects, for Dr. Fernald presents convincing proof that all difficulties in learning to read, spell, write, or figure, in a child of normal or superior intelligence, can be removed or compensated for if the proper technique is employed. An important influence in the direction of solution of this great problem may come from the ophthalmologists' interest and advice to the parents and teachers of these children.

To quote in conclusion from the Foreword by Prof. Lewis Terman of Stanford University: "Perhaps the most important conclusion to be drawn from the extensive researches here reported is that disability of any degree in any of the basic school subjects is wholly preventable. If educational methods were more intelligently adapted to the idiosyncrasies of the

individual child, all children could achieve up to their mental age level in all school subjects. It is largely for this reason that I believe this book is one of the most significant contributions ever made to experimental pedagogy."

S. Rodman Irvine.

OBITUARY

ADOLPH O. PFINGST

1869-1944

Dr. Adolph O. Pfingst was born in Louisville, September 8, 1869. After

Adolph O. Pfingst

graduating from high school in Louisville and securing a B.A. from the University of Louisville, he entered the medical de-

partment, from which he obtained his medical degree in 1891. Competitive examination awarded him the appointment of resident in the Louisville City Hospital, where he spent a year in rotating service. He then filled an unexpired term on the surgical staff of Mt. Sinai Hospital, New York, before going to Europe to take up the study of ophthalmology.

After a year of work in the laboratories at Marburg, pursuing the study of pathology under Professor Marchand and bacteriology under Prof. Carl Fraenkel, he began his studies in ophthalmology under Professors Uthoff and Axenfeld. In 1893-1894 he was assistant to Professor Schweiger in the University Eye Clinic in Berlin. While there he wrote his thesis and obtained a "Doctor of Medicine" from the University of Berlin.

In 1895, Dr. Pfingst became assistant to Prof. Herman Knapp and house-surgeon to the New York Ophthalmic Institute for a year. He then established himself in Louisville, Kentucky, as an ophthalmologist and associated himself with bacteriologic and histologic laboratories. He established a reputation as a dynamic instructor and was popular with the student body. In 1906, he was promoted to the chair of Professor of Ophthalmology and Director of the Eye Clinic at the Louisville City Hospital. He retired from active teaching in 1938, when the title of Professor Emeritus was conferred upon him.

Dr. Pfingst was a fellow of the American College of Surgeons and was also a member of the American Ophthalmological Society; the Academy of Ophthalmology, Otology, and Laryngology; member of the International Society of Ophthalmology and the Pan-American Congress of Ophthalmology. He also held membership in the American and Southern Medical Associations, the Kentucky

State and Jefferson County Medical Societies, and was active in various medical clubs in Louisville. He was instrumental in organizing the Kentucky State and the Louisville Eye and Ear Societies, each of which he served as president.

Dr. Pfingst was always interested in civic affairs of his home town and was organizer of the first sight-saving class in Louisville; he was active in the national movements for the prevention of blindness.

He contributed to scientific medical literature, his interest being especially centered on pathologic studies of the eye and on diseases and anomalies of intracranial blood vessels.

Since 1930 Dr. Pfingst has had Dr. C. Dwight Townes associated with him in his surgical and office work.

Dr. Pfingst had one daughter, Katherine, who died in 1918. He is survived by his wife, Mrs. Lula Pfingst.

Irwin Abell.

CORRESPONDENCE

1944 MEETING OF THE LOS ANGELES RESEARCH STUDY CLUB

Editor, American Journal of Ophthalmology:

The thirteenth annual Post-Graduate Clinical Course of the Research Study Club of Los Angeles was held January 17th to 29th. Registrants for the course numbered 311, among them 52 service men; 31 states were represented.

The visiting teaching staff for ophthalmology included Dr. James Watson White, who gave the principal lectures of the Eye Course on "Motor anomalies"; Dr. Georgiana Dvorak Theobald, who reviewed certain aspects of "Eye pathology"; Dr. Meyer Wiener and Dr. Frederick Carl Cordes, who gave instructions and demonstrations on "Surgery of the

eye"; Dr. George Hosford, who assisted Dr. White in the instruction courses, demonstrating muscle cases; and Mr. Irving Lueck of Bausch and Lomb Company, who lectured on "Optics of ophthalmic lenses," "Cross cylinders," "Lighting and colored lenses," and "Selection of bifocals." The main otolaryngologic speakers were Dr. Isidore Friesner, Dr. Gordon B. New, Dr. Arthur W. Proetz, Dr. Samuel Salinger, and Dr. Carl H. McCaskey.

Again this year, following the John Finch Barnhill tradition, a course in "Applied anatomy and cadaver surgery of the head and neck" followed the regular course, January 28th to February 1st.

The large attendance, in spite of wartime inconveniences, justified the attitude of the Research Study Club that postgraduate teaching should be continued during the war years as a means of insuring the best possible medical protection to the country.

It is hoped that the lectures of the principal speakers will be available for publication in the Journal.

Dr. White's course brought to the Research Study Club the Duane school of thought on ocular muscles. In some respects this differs from Bielschowsky's teachings, which were presented in this course in 1938. Combining the ideas from both these authorities will lead to a broader understanding of muscle problems. Dr. White emphasized the use of the cover test and the screen comitance test. He does not rely upon the measurement of diplopia for diagnosis, as did Bielschowsky, but instead neutralizes with prisms the movement of the eyes brought out by the cover test in the six cardinal positions. No one is as responsible for popularizing this objective method for measuring eye deviations as is Dr. White. In addition he has simplified recording of these deviations, so that muscle tests are not so com-

plicated nor time-consuming as previously.

Dr. White does not rely on the head-tilting test to differentiate oblique from vertical recti involvement, as did Bielschowsky. His explanation of double hyperphoria as being involvement of corresponding vertical muscles in the two eyes, differs from that of Bielschowsky, who considers this phenomenon as supranuclear innervational disorder. This disparity in ideas relative to use of the head tilt in diagnosis of oblique abnormalities, and the origin of double hyperphoria, offer fields for confirmatory investigation.

As the various types of anomalies were discussed, with their infinite variations, the lecturer's intimate personal contact with the solution of muscle problems was appreciated by those in attendance in proportion to their experience in muscle work. It was extremely instructive to hear Dr. White discuss specific cases such as have worried all of us as one who has encountered the problem many times and considered and treated it from varied points of view. In summary, the course stressed the practical side of muscle work. Consequently the sensory aspect of motor anomalies, as abnormal retinal correspondence, inhibition, and amblyopia, were but briefly touched upon.

In the reviewer's opinion the outstanding lectures by Dr. Theobald were those on the "Anatomy and histology of the anterior segment of the eyeball with reference to the canal of Schlemm," on "Eye infections," and on "Intraocular tumors." Dr. Theobald demonstrated her serial sections, showing direct communications from the anterior chamber through the canal of Schlemm to the vascular system about the extraocular muscles.

Her discussion of the use of calcium gluconate in eye infections was new to many of us and will add to our therapeutic armamentarium.

Her classification of intraocular tumors as to malignancy will be of definite benefit to members of the Course in decisions as to the prognosis in and treatment of such cases.

Dr. Wiener and Dr. Cordes demonstrated, along with other operative procedures, Dr. Wiener's operation of forming a union between the levator and superior-rectus muscles for correction of ptosis.

Mr. Irving Lueck's interesting lectures on optics were extremely practical, easily

understandable, and are available in reprint form.

This annual Course is unique in that it is designed to attract the general eye, ear, nose, and throat practitioner who is seeking a solution to his everyday problems, as well as the academic-minded specialist to whom it affords an opportunity to meet world-known authorities and discuss with them, through the arrangement of courses and entertainment, the particular interests or problems he has in mind.

S. Rodman Irvine.

THE FORM AND CHARACTER OF ROD SCOTOMETRY

AIR COMMODORE P. C. LIVINGSTON

(Concluded from page 353)

early stage in vitamin-A deficiency (fig. 5). This condition has been recorded while the subject continues to provide a normal adaptometer curve. This divergent result seems explainable on the grounds that while with the adaptometer a selected patch of retina is subjected to the test, with a screen a wide area is examined by means of a moving target. The question of movement which increases the spread of the threshold visual sensation must be regarded as of significance.

Pathologic features. It will suffice to illustrate the field appearances of one pathologic condition (fig. 6). In cases of diabetes, small lozenge-shaped scotomata appear, dotted irregularly about the field. This is accentuated under states of reduced-oxygen tension. There appears to be a close association between the scat-

tered areas of deficiency revealed on the screen and the nutritional disturbances in the retina that are brought about through capillary embarrassment.

SUMMARY

Scotometry, employing self-luminous test objects and a red fixation light, appears to reveal defects in the central field of vision which cannot readily be found by customary procedures. It is well to confine this method to the 30-degree screen. Up to this point, it is possible to work with very low luminosities, such as 4×10^{-9} or 6×10^{-9} candle power, without introducing physiologic effects likely to be confused with early pathologic conditions. Further work is being undertaken to improve equipment and technique, so as to establish normal field characteristics.

R.A.F. Kelvin House, Cleveland Street.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

1

GENERAL METHODS OF DIAGNOSIS

Kronfeld, P. C., and McGarry, H. I. **Present limits of gonioscopy.** *Amer. Jour. Ophth.*, 1944, v. 27, Feb., pp. 147-153. (One table, references.)

Pitman, L. K. **A combined ophthalmoscope and retinoscope.** *Arch. of Ophth.*, 1943, v. 30, Nov., pp. 667-668.

The author describes the construction of an instrument that can be used as either an ophthalmoscope or a retinoscope. (One illustration.)

R. W. Danielson.

2

THERAPEUTICS AND OPERATIONS

Arjona, J. **Subconjunctival auto-hemotherapy.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Aug., pp. 140-155.

One c.c. of blood taken from a vein in the patient's arm is injected beneath the bulbar conjunctiva in various allergic and inflammatory affections of the eye. The blood is absorbed within 6 to 15 days. Several injections may be necessary. Beside the curative effect

the striking relief of pain is an important benefit. The injections have been found very efficacious in tuberculous keratitis, trachomatous pannus, rheumatic iritis, scrofulous keratoconjunctivitis, and reactions of sensitivity to atropine and eserine. In the latter it has been possible to continue the use of atropine or eserine after an injection. Conditions not benefited were hypopyon ulcer, luetic interstitial keratitis, and tuberculous, traumatic, or postoperative iritis. With the blood injected locally, the author argues that the circulating antibodies are brought to bear directly on the eye.

J. Wesley McKinney.

Atkinson, W. S. **Local anesthesia in ophthalmology.** *Arch. of Ophth.*, 1943, v. 30, Dec., pp. 777-808.

The history of the use of local anesthetics in ophthalmology is reviewed. General conditions affecting anesthesia are discussed, including the distribution of sensory nerves to the orbit and the mental attitude of the patient and surgeon. After describing the various local anesthetic agents, the author concludes that tetracaine is the best drug

for surface instillation and that procaine is the most suitable for injection. The effect of procaine injection is improved by the addition of epinephrine.

Detailed directions are given for the production of intradermal wheal, nerve block, and field block. Retrobulbar injection into the muscle cone, block of the infraorbital nerve, block of the infratrochlear nerve, facial akinesia, and so forth are explained. The appropriate methods of anesthesia for the commoner ophthalmic operations are described. Techniques are described in such detail and with such a practical approach that the article should be of value even to ophthalmic surgeons of long experience. (16 illustrations, bibliography.)

John C. Long.

Bieltiukova, A. A. Roentgen therapy of some ocular diseases. *Viestnik Oft.*, 1943, v. 22, pt. 2, pp. 35-40.

A review of the literature, and a report of the author's clinical investigations on 45 patients. Roentgen therapy was found very effective in chronic tuberculosis of the anterior ocular segment. The initial dose was 10 to 20 percent of the erythema dose, and three or four treatments were given at intervals of 12 days. An acute reaction lasting several days after the treatment was frequent. In some cases, immediately after the irradiation, there developed around the inflammatory focus transitory gray streaks, radiating from the center toward the periphery. The effects of the treatment included subsidence of inflammatory phenomena, visual improvement, and absence of recurrence. Twenty patients with other diseases were subjected to this form of therapy. It was ineffective in trachoma, in traumatic iridocyclitis, and in leukoma. It checked suppuration in the vitreous in a case of traumatic endoph-

thalmitis, but the eyeball went on to atrophy. In two cases of secondary glaucoma this treatment relieved the pain. A fistula of the lacrimal sac closed after irradiation. Ray K. Daily.

Buxton, R. Anesthetics for ophthalmic operations. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 179-182.

The author insists that the aim of anesthesia is to reduce fear and apprehension to a minimum, and to abolish pain, without incurring risk to the eye or to the patient. Premedication is indicated to lessen apprehension as well as to aid in the effect of the local anesthesia. In cataract operations, facial-nerve block is advised, as well as subconjunctival injection at the points of fixation. In acute glaucoma or acute iritis a pledget of cotton soaked in 5-percent cocaine with adrenalin and placed on the conjunctiva preliminary to the subconjunctival injection has aided anesthesia a great deal. In detachment of the retina the patient should receive extra sedation, and repeated local instillations as may be necessary to continue a painless operation. For dacryocystectomy, careful injection of the infraorbital and infratrochlear nerves is advised.

Beulah Cushman.

García Miranda, A. Alterations of refraction in the course of sulfonamide therapy. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Sept., pp. 305-307. (See Section 3, Physiologic optics, refraction, and color vision.)

Green, E. W. The present status of sulfonamides in ophthalmology. *The Mississippi Doctor*, 1943, v. 21, July, p. 35.

In the treatment of bacterial diseases

sulfonamides aid principally by their bacteriostatic action. Following oral administration, the concentration of sulfadiazine in the aqueous seems greater than that of sulfanilamide or sulfathiazole, but the latter increases in the presence of ocular infection. Sulfonamides are excreted by the kidneys, sulfapyridine in its acetylated form being responsible for renal calculi. Toxic effects vary from cyanosis and gastric upsets to fever, rash and leukopenia.

Oral sulfonamides are employed by the author in severe cases of acute conjunctivitis. They have unquestioned value in gonorrheal conjunctivitis, but their exact role in trachoma is somewhat in dispute, with most observers agreeing that there is clinical improvement. Favorable results have been obtained in inclusion conjunctivitis, blepharitis, corneal ulcer, and cellulitis of lids and orbit. The merit of these drugs in other ocular diseases has not been so clearly demonstrated.

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Allen, M., Flack, F., and Billings, M. L. Three pedigrees of eye defects. (Nystagmus and myopia.) *Jour. of Heredity*, 1942, v. 33, Dec., p. 453. (See Section 17, Systemic diseases and parasites.)

Argañaraz, R. Chromatoscopic case for the diagnosis of color blindness. *Arch. de Oft. de Buenos Aires*, 1942, v. 17, May, p. 247.

To overcome the inadequacy of the Holmgren and Edridge-Green color tests, and to avoid the patient's memorizing the Stilling-Ishihara plates for the detection of color blindness, the author presents a chromatoscopic case of his own design. It consists of a box with two holes, the borders of which are painted with pure spectral red and green. There are twenty-four beads giving different hues of red and green and also confusion colors. During the test the patient drops the beads through the holes of matching color, and the results can be quickly observed by examining the beads fallen in the compartments under the two respective holes. (Color illustration.) Plinio Montalván.

Burian, H. M. Influence of prolonged wearing of meridional size lenses on spatial localization. *Arch. of Ophth.*, 1943, v. 30, Nov., pp. 645-666.

When a meridional size lens is placed with its axis at 90 degrees in front of one eye of a normal observer, the retinal image of that eye is enlarged in the horizontal meridian. Since horizontal disparity of the retinal images is responsible for stereoscopic effects, the observer will experience typical changes in the appearance of his environment. The author planned the present work to answer the following questions: What happens to the appearance of space and to an observer's functioning within space when a meridional size lens is worn constantly for a certain length of time? Do the spatial distortions of the normal surroundings remain unchanged? Does the rotation of the horopter curve remain the same? Does the capacity of compensating for artificially introduced meridional aniseikonic errors exist?

Experiments are reported in which three observers wore a meridional size lens at axis 90 degrees in front of one eye for 8 to 14 days. After a technical discussion of the data, the author concludes in part as follows:

When a person with normal binocular vision places a meridional size lens at axis 90 in front of one eye and wears this lens for several days, he at first experiences a typical distortion of his surroundings. The longer the lens is worn, the less the distortion is noticeable, and it finally disappears and is absent as long as the observer remains within roundings abounding in perspective and other uniocular elements.

However, if the number of effective perspective factors in the surroundings is negligible, the distortion recurs immediately, and measurements made

with instruments from whose field of view these factors are absent show that the larger part of the image size-difference is still present, no matter how long the size lens has been worn. But there is an average decrease in the effectiveness of the size lens of from one fifth to two thirds as measured with these instruments. This decrease in effectiveness could be due either to a process of actual physiologic compensation, leading to a redistribution of the stimuli on the retinas, or to a psychologic reinterpretation of the relation of objects in space under the influence of uniocular clues in the surroundings and of memory values of past experience. R. W. Danielson.

Butler, T. H. Forty-eight years of refraction. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 247-255.

The author emphasizes that the object of refraction is to make the patient comfortable, not to solve a problem in optics, yet he also states that an infant with poor acuity will probably become unobservant and develop unsocial habits.

Some of the difficulties brought out relate to the necessity of examining the macular area to get the proper reading in the retinoscopic examination, the danger of insufficiency of cycloplegia when this is used, and the necessity of checking the binocular vision with the correction and adjusting accordingly for the final prescription. (One graph.)

Cotlier, I. Applications of the stenopaic slit in refraction. *Arch. de Oft. de Buenos Aires*, 1942, v. 17, May, p. 266.

The author discusses at length the optical principles of the stenopaic slit,

which he finds of practical value in measuring the refractive error and in determining whether an ametropic eye has been accurately corrected with lenses. (Diagrams, bibliography.)

Plinio Montalván.

Cotlier, I. The velonoskiascope. Rev. Oto-Neuro-Oft., 1942, v. 17, Jan.-Feb., pp. 13-21.

This instrument of refraction, not in general use in this country, is based on the observations of Holth, who noted that when a needle was slowly moved before an ametropic eye which was fixing a light at 5 meters, a shadow formed whose movement depended upon the type of refractive error present in the examined eye. The shadow takes the form of the needle, and does not exist in an emmetropic eye. If the eye is hypermetropic and uncorrected, the movement of the shadow is against the movement of the needle; the opposite is true of myopia. In simple astigmatism a shadow exists only in the axis of the astigmatism and may be removed by placing a correcting cylinder before the eye. In cases of compound astigmatism and mixed astigmatism, corresponding findings obtain with regard to the movement of the shadow—against in hyperopia and with in myopia.

Instead of Holth's primitive apparatus, the author has devised a compact instrument, the velonoskiascope (from the Greek word for a needle), which consists of a stand, a round, revolvable disc with meridian-finders, and a central illuminated slit covered with milk glass. With this instrument and trial lenses he can determine both spheric and cylindric corrections. One of the disadvantages of the apparatus is that it requires a high degree of coöperation by the patient. However, it has the ad-

vantage of minimizing any error due to an examiner's possible inexperience, of utilizing macular vision, and of being more refined than the simple skiascope, especially in cases of scissors movement, miosis, and small corneal or lenticular opacities.

Crozier, W. J., and Wolf, E. Theory and measurement of visual mechanisms. 9. Flicker relations within the fovea. Jour. Gen. Physiology, 1943, v. 27, Nov., pp. 119-138.

The investigation described in this highly technical article aims to determine flicker recognition contours within the human fovea with reference to light-time fraction (t_L) and wavelength composition as controlled parameters, and also considers the areas and form of the test patch. It deals further with conclusions arising from the study of reasonably homogeneous data on flicker recognition as a function of flash frequency and flash cycle form, flash intensity, image area and form, retinal location, wavelength composition of the light, and the fraction of the cycle-time occupied by light.

The authors state that "white" must be regarded as a synthesis, not a mere summation, of effects due to different spectral regions. Attention is called to certain differences between foveal and more peripheral regions tested, and as between observers differing in the degree of the "yellow spot effect," with regard to the relative effects of wavelength and of image area.

W. H. Crisp.

Dunlap, Knight. Mental maladjustment and color vision. Science, 1943, v. 98, Nov. 26, p. 470.

Since a number of cases of parachromopsia (so-called "color-blindness")

were found among persons who gave a history of dietary insufficiency, especially lack of meat in the diet, and since neurotic stammerers are (according to the author) usually not meat eaters, the author was interested in testing the color vision of persons suffering from neurotic maladjustment. Twelve neurotics were selected for the color-vision test. The Ishihara charts and Lohen's revision of the Nela tests were used. Of the 12 only one was found to have completely normal color vision.

The author further criticizes the present method of color-vision examination at close range, whereas the practical requirements call for recognition of color at a great distance. The author, moreover, postulates that color vision should in general be tested under conditions similar to those in which the colors are used. R. Grunfeld.

García Miranda, A. Alterations of refraction in the course of sulfonamide therapy. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Sept., pp. 305-307.

A 26-year-old man was given 22 grams of the sulfonamide "uliron" over a period of 17 days. After 24 hours his vision became suddenly blurred, being reduced to O.D. 1/6 and O.S. 1/8. The corneal astigmatism was 0.5 diopter each eye, as measured by the ophthalmometer, and remained the same for the duration of the disturbance. Refraction revealed O.D. -2.00 sph. -2.00 cyl. ax. 60° = 1.0, and O.S. -2.00 sph. -2.00 cyl. ax. 120° = 1.0, unchanged by repeated instillation of atropine. Administration of uliron was discontinued and within four days the

vision was 1.0 each eye without correction. The disturbance apparently resulted from absorption of the sulfonamide by the lens.

J. Wesley McKinney.

Lister, A., and Bishop, J. W. Night vision in the Army. *Brit. Med. Jour.*, 1943, Sept. 11, p. 325.

The results of 10,333 tests for night vision on high-category men between the ages of 18 and 55 years are tabulated. Though the test is one of form sense, it appears that the minimum light necessary for discrimination of a simple form is in the region of the absolute light threshold. Classification illustrates the downward trend of scotopic vision which occurs with advancing years. This point is more of theoretic interest since the drop from the average at 18 to that at about 44 years is only in the region of 3 micromillilamberts.

McFarland, R. A., Hurvich, L. M., and Halperin, M. H. The effect of oxygen deprivation on the relation between stimulus intensity and the latency of visual afterimages. *Amer. Jour. Physiology*, 1943, v. 140, Dec., pp. 354-366.

The relationship between the latency of visual afterimages and stimulus intensity during exposure to various atmospheric oxygen tensions is shown in tabulated form. These data are based on six experimental sessions employing three trained subjects. Each session consisted of a series of measurements in normal air followed by repetitions during anoxia; and finally 100 percent

oxygen was administered and observations repeated after recovery intervals.

The conclusions reached are that the effect of oxygen deficiency on the latent time of the "tertiary" visual afterimage, measured in a low oxygen chamber over a wide range of stimulus intensities, shows that in normal air there is an inverse relationship between the latent time of the afterimage and the intensity of the stimulus, reduction of the intensity of the stimulus prolonging the latency of the afterimage. Anoxia prolongs the latency of the afterimage. Complete recovery of the latent time upon administration of oxygen may require up to fifty minutes and the apparent brightness of the visual field is restored to normal within three to four minutes. The behavior of the visual mechanism is believed to reflect changes in the central nervous system, since the retina is embryologically a part of the central nervous system and resembles it metabolically and anatomically. Slowness of recovery of the function is therefore indicative of a similar delay in the recovery of other central nervous functions. This emphasizes the importance of the use of oxygen by airplane personnel at high altitudes as a preventive measure, before any appreciable effect of anoxia occurs. The possibility that some central nervous functions recover slowly after anoxia suggests that certain factors contributing to landing accidents at sea level after high altitude flights without an adequate oxygen supply may be attributed to the residual effects of lack of oxygen. Melchior Lombardo.

Miles, W. R. Color blindness in eleven thousand museum visitors. *Yale Jour. Biol. and Med.*, 1943, v. 16, Oct., p. 59.

By Ishihara charts, 7.1 percent of eight thousand men were found defective in color vision, and 1.3 percent of three thousand women were similarly defective.

Six grades of color defect were proposed, arranged in order of diminishing defect from group I to group VI. Group IV includes typical dichromates and extreme anomalous trichromates. The author suggests that groups I to IV ought to be disqualified for service with the air force, whereas groups V and VI should be relatively safe risks. Groups I and II are entirely unsafe where recognition of colored signals is important. The author states that pseudo-isochromatic charts presenting colored forms of the vanishing pattern type on neutral gray backgrounds of similar brightness constitute a rapid practical means for determining degrees of color defect.

Robert N. Shaffer.

Obrig, T. E. A new ophthalmic impression material. *Arch. of Ophth.*, 1943, v. 30, Nov., pp. 626-630.

The satisfactory fitting of contact lenses became a possibility when it was discovered that molds of the living human eye could be made with negocoll. However, negocoll has certain disadvantages and the present paper deals with the author's experience with a new medium called moldite powder—for which the manufacturer refuses to divulge the formula. It is an alginate gelling agent which reacts when mixed with distilled water. The gelling is retarded by a preparation which gives sufficient time for the material to be placed on the eye and the molding shell centered before the gelling takes place.

The many advantages of moldite

powder over negocoll are well outlined and the technique of its use is given in orderly and meticulous detail. (2 figures.) R. W. Danielson.

Orton, S. T. Visual functions in strephosymbolia. *Arch. of Ophth.*, 1943, v. 30, Dec., pp. 707-711. (See Section 12, Visual tracts and centers.)

Pascal, J. I. A new approach to cross-cylinder tests. *New York State Jour. Med.*, 1943, v. 43, Feb. 15, p. 323.

For every astigmatic eye in a state of rest, one spherical lens gives better visual acuity than any other spherical correction. This "spherical equivalent" represents that correction in which Sturm's conoid straddles the plane of the retina so that a round diffusion circle is focused on the retina—a state of equally mixed astigmatism.

If an eye is so corrected that it is placed in such a state of equally mixed astigmatism as mentioned above, then the cross cylinder may be used to best advantage in determining the presence of, and axis of, astigmatism. In such a condition, the patient appreciates differences in the two positions of the cross cylinder by differences in the size of the diffusion circles.

One table in the paper illustrates the fact that the difference in size of diffusion circles is greater, the stronger the cross cylinder used (providing it is held so that one axis of the cross cylinder is at or very near the axis of astigmatism), until one reaches a cross cylinder equal in cylinder strength to the existing astigmatism. Under these conditions, there will be a maximum diffusion circle in one position, and none at all in the other position. Thus one should use a stronger cross cylinder. The difference in size of circles de-

creases as the cylinder axes become more obliquely inclined to the axis of astigmatism, until at 45 degrees to the astigmatic axis there is no difference.

Using this same "spherical" approach for determining the axis of astigmatism, the best effect is obtained by the use of correcting cross cylinders, as well as the testing cross cylinder. As the cylinder strength increases (both correcting and testing), the difference in size of diffusion circles increases. One table shows the results obtained with a fixed combination of 0.25 correcting cross cylinder and 0.50 testing cross cylinder. This combination proves to be satisfactory in most cases. Within 5 or 10 degrees, however, a more exact method would be the use of a testing cross cylinder half the strength of the correcting one. This step may be used, as a final check on the axis, after the cylinder strength has been determined.

For determining the amount of astigmatism, a stronger cross cylinder is preferable, in early stages of the test, utilizing correcting cross cylinders to maintain the same spherical equivalent.

Benjamin Milder.

Pember, A. H. Presbyopic analysis. *Dis. Eye, Ear, Nose, and Throat*, 1942, v. 2, Dec., p. 364.

In addition to a proper refraction, measurement of accommodation convergence and interpupillary distance is considered of great importance in giving comfort to wearers of presbyopic corrections. Methods used in these determinations, other than the actual refraction of the patient, are described. The prismatic effect of certain lenses is discussed briefly.

Most refractionists are said to overcorrect their patients for near use. The author discusses a modification of the

use of the ampliometer with reference to additions for near use of the eyes.

F.-M. Crage.

Pett, L. B. Riboflavin and vitamin A in relation to "eye strain". Canadian Med. Assoc. Jour., 1943, v. 49, Oct., pp. 293-295.

A three-months study was made on 232 men and women whose vocation was reading handwriting under normal lighting conditions and who complained of "eye strain." The ages varied from 20 to 70 years. Conjunctival opacities as seen with the biomicroscope constituted apparently the sole evidence of vitamin-A deficiency, and blood vessels crossing the limbus between the 5 and 7 o'clock positions were the sole evidence of riboflavin deficiency. The large group was divided into three equal small groups. One group received a capsule of 10,000 i.u. of vitamin A daily; the second, 3 mg. of riboflavin daily; the third, a capsule containing inert matter. The patients did not know the nature of their medication. In no case was the diet supposed to be changed. In the vitamin-A series, as judged by the above biomicroscopic criteria, 12 percent of those with deficiencies improved after three months of 10,000 i.u. of vitamin A daily. In the riboflavin series, 57 percent of those with deficiencies improved after treatment, but 47 percent improved without any treatment. Charles A. Bahn.

Prado, Durval. Concerning Márquez' biastigmatism. Arquivos Brasileiros de Oftalmologia, 1943, v. 6, June, pp. 100-104.

The author briefly indicates the nature of Márquez' technique. The astigmatic test is begun by measuring the corneal astigmatism with the ophthalmometer and then using skiascopy and

subjective tests to measure separately the "residual astigmatism." The author remarks that many ophthalmologists have convinced themselves of the necessity for prescribing one-eighth diopter intervals, whereas some large manufacturers of correcting lenses do not make lenses having such intervals.

W. H. Crisp.

Salvatori, P. L., and Oriani, A. The fitting of contact lenses. Arch. of Ophth., 1943, v. 30, Dec., pp. 763-766.

Molded plastic contact-lenses must often be adjusted to fit the individual eye. The authors have worked out a method of making these adjustments according to plan. In the fitting of contact lenses, one must bear in mind the convergence of the eyes, the pressure of the lids, and the effect of gravity. To compensate for these factors, a contact lens should be fitted so that the corneal portion will be decentered upward and turned slightly toward the nose. When fitted correctly the lens should rest uniformly on the sclera without constricting the blood vessels. There should be no tight or loose areas.

The contact lens is first checked for over-all size. Instructions are given for trimming away the margins if they exceed the fairly definite size limitations. Rotation is studied after marking the lens with a horizontal line, and is controlled by relieving excessively tight areas or by tightening loose edges. Tight or loose areas are detected by instilling fluorescein and suitable correction is obtained by grinding with a grit-impregnated rubber point on a dental machine. Optical centering is determined after marking the pupillary center on the plastic while the lens is in the eye. A blue-print-like record of the corrective markings is made in every case. This is an indispensable aid

to the fitter, serving as a permanent record and as a basis for planning necessary adjustments. Much time is saved and a more comfortable fit is obtained by following a definite plan rather than by free trial-and-error methods. (2 color plates.)

Dolph, C. H. The cover test as an aid to diagnosis in extraocular muscular anomalies. *Texas State Jour. Med.*, 1943, v. 38, Feb., p. 612.

Dolph calls attention to the cover test. Because of its simplicity it is often neglected. T. M. Shapira.

Foster, C. B. A new suture for use in muscle-recession operations. *Amer. Jour. Ophth.*, 1944, v. 27, Jan., pp. 71-72.

Gamble, R. C. High congenital myopia with convergent strabismus. *Amer. Jour. Ophth.*, 1944, v. 27, Feb., pp. 159-160.

Grieve, J., and Archibald, D. H. Some facts and figures relating to heterophoria in symptom-free individuals. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 285-293.

The authors report on a study of heterophoria in a selected group of air recruits between the ages of 17½ and 30 years. Out of 7,019 men examined, 53 percent showed lateral, vertical, or both deviations, and only 1.3 percent complained of symptoms. Voluntary convergence was found in 30 percent of 1,268 recruits examined.

The second part of the paper gives results of an investigation into the incidence of convergence insufficiency among normal school children. Of 104 children examined, 8 percent showed heterophoria, and 58 of these children had voluntary convergence. In comparing the development of the child intellectually and emotionally with the above findings, out of 58 children with perfect voluntary convergence 30 were considered normal, 17 intellectually retarded, and 11 unstable. Of the 46 without the power of voluntary convergence 14 were regarded as normal in

all ways, 8 intellectually retarded, and 24 unstable.

The third part of the paper deals with findings in a group of retarded children. Of the 86 examined, 52 did not have full voluntary convergence. Of these, twenty were intellectually retarded and 32 emotionally unstable.

Facts of special interest are the disparity between the number of individuals showing phorias and the number with symptoms, the high incidence of poor voluntary convergence in all groups, and the high incidence of esophoria for distance and of exophoria for near among adults.

Kobrak, F. Studies on vestibular nystagmus. *Jour. Laryng. and Otol.*, 1943, v. 58, May, p. 167.

The author describes his studies carried on with weak caloric stimulus on the labyrinth in preference to the rotatory test, and he discusses his observations on latent nystagmus. These experiences may serve as a diagnostic aid for detection of abnormalities of the acoustic nerve.

R. Grunfeld.

Krimsky, Emanuel. Fixational corneal light reflexes as an aid in binocular investigation. *Arch. of Ophth.*, 1943, v. 30, Oct., pp. 505-520; also *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1943, 47th mtg., March-April, p. 269.

Ocular deviation and binocular imbalance may be measured in a controlled and graded objective manner by artificial restoration of the corneal light reflexes to their fixation positions. Artificial restoration, or centering, of the

corneal light reflexes may be carried out with prisms, the anglo-meter, the phorometric stereoscope, or the synoptophore.

The amount of deviation in a squint may be measured by the strength of prism required to center the corneal light reflexes. It is not intended that this determination replace the familiar cover test. The observation of the light reflex is also of value in objectively determining the amount of prism convergence and divergence, in measuring heterophoria, in distinguishing a heterophoria from a heterotropia, in measuring squint with severe amblyopia, and in demonstrating malingering. In addition, the fixational corneal light reflexes are helpful in the objective study of the near point of convergence, ocular dominance, primary versus secondary deviation, ocular torticollis versus sternocleidomastoid torticollis, the range of monocular movements, binocular fixation, abnormal retinal correspondence, and pseudostrabismus. (12 figures.)

John C. Long.

Malbrán, Jorge. Paralysis of the inferior rectus muscle. *Arch. de Oft. de Buenos Aires*, 1942, v. 17, May, p. 311.

A 29-year-old woman presented a paralysis of the left inferior rectus muscle following a blunt injury to the orbit. The pupil was dilated and irresponsive to the different stimuli in the affected eye. An atypical torticollis, with the head tilted to the right side, was also present. The author discusses the diagnostic significance of this torticollis and the neural mechanism of the mydriasis, as well as the pupillary response to pharmacodynamic tests. From the use of eserine and pilocarpine, which produced marked miosis in this case, he concludes that the lesion was located behind the ciliary ganglion, and

was probably a traumatic hematoma of the orbit. Myectomy of the paralyzed muscle resulted in disappearance of the torticollis and diplopia. The mydriasis was gradually subsiding. (Photographs, bibliography.)

Plinio Montalván.

Mata, P., and Carrillo, E. A case of Erb-Goldflam disease (myasthenia gravis). *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Sept., pp. 233-250.

The case reported is that of a 14-year-old girl who for the preceding three years had had a mild ptosis of both upper lids of variable degree associated with transient attacks of diplopia. The ptosis was worse in the evening and after exertion. No other muscles were affected although there was a general asthenia with fatigue after much walking. The myasthenic reaction of Jolly was positive. (This test consists in repeated galvanic stimulation of the affected muscles, which in this syndrome show rapid fatigability to the point of complete absence of response to the electrical stimulation.)

The author points out that in most cases of myasthenia there is a disturbance in the metabolism of lactic acid and creatinin with an increase in both blood and urine. In this case, however, there was no increase in the blood lactic acid. Creatinin was markedly increased in the urine. The symptoms were relieved and controlled by glucococcol. Prostigmin was not available to the authors. J. Wesley McKinney.

Prangen, A. D. Surgical treatment of paralysis of the rectus muscles of the eye. *Proc. Staff Meetings Mayo Clinic*, 1943, v. 18, May 19, p. 145.

The author presents a case of bilateral traumatic paralysis of the external recti muscles. Transplantation of the inferior and superior recti, a 13-mm. resection of the external recti, and a 6-mm. recession of the interni were performed. This extensive surgery was well tolerated and resulted in straight eyes, obliteration of the diplopia, and normal excursions. F. M. Crage.

Roth, E. V. Orthoptics for the infant squinter, one to four years old. *Amer. Jour. Opth.*, 1944, v. 27, Jan., pp. 57-60.

Stewart, D. D. S. A method of evaluation of binocular muscle balance. *Brit. Jour. Opth.*, 1943, v. 27, Nov., pp. 477-483.

As a part of all routine eye examinations, estimation of the dynamic ocular equilibrium for distance as well as for near is recommended. Two instruments are described to assist in rapid estimations of muscle balance: (1) a pair of 7-D. prisms, bases out, in a hand spectacle-frame; (2) a spring mount with a thin handle to take a single trial lens (a 2-D. prism). The fixation target used consists of a Snellen chart on a black ground with a white diamond-shaped card above the chart and a white ring and a dot on either side of the chart.

Tests for esophoria, exophoria, and hyperphoria are described. No attempt is made to indicate how an examiner may use the information gained from these tests, since every oculist has acquired by experience an opinion on measures likely to relieve symptoms of visual discomfort. It is the author's opinion that we do not yet appreciate the extent to which selected adult patients can be helped by "eye exercises" of the right kind. (3 illustrations.)

Edna M. Reynolds.

Sugar, H. S. Guides in the operative (cosmetic) treatment of nonaccommodative concomitant squint. *Arch. of Ophth.*, 1943, v. 30, Nov., pp. 593-602.

In view of the many variable reports on the amount of correction obtainable by various operative procedures, the author has analyzed 65 operations on the internal and external rectus muscles of male Army personnel, ranging in age from 20 to 49 years. The resection operation used was the Lancaster procedure. The recession operation of Jameson was utilized.

The results cannot be easily abstracted and should be read in full. The average values are fairly consistent. Resection of the internal rectus muscle resulted in more correction than did recession of that muscle. The opposite result was obtained with operation on the external rectus muscle, where recession was generally more effective. Seven-mm. recessions were done in some cases in spite of the fact that it is standard procedure not to do a recession of more than 5 mm. on the internal rectus muscle or of more than 3 mm. on the external rectus muscle.

In convergent-squint cases of the convergence-excess type, recession of the internal rectus muscle should be the primary procedure. For deviations up to 15 prism-diopters, recession of the internal rectus muscle of the deviating eye is recommended. With greater degrees of strabismus, resection of the external rectus muscle should also be done. In the convergence-insufficiency type, for deviations up to 16 prism-diopters resection of the internal rectus muscle of the deviating eye is recommended. For deviations of 16 to 25 prism-diopters resection of both internal rectus muscles or resection of the internal muscle of the deviating eye, and recession of the external rectus

muscle of the same eye, depending on the deviations for distance and near vision, are indicated.

In divergent-squint cases of the divergence-excess type, recession of the external rectus muscle of the deviating eye should be the primary operation. In the divergence-insufficiency type, resection of the internal rectus muscle is then the primary operation. Recommendations are also given for the divergence-excess and divergence-insufficiency types. (5 tables, references.)

CONJUNCTIVA

Bedell, A. J. Distribution of epidemic keratoconjunctivitis in the United States. *Jour. Amer. Med. Assoc.*, 1943, v. 123, Dec. 25, p. 1101.

Keratoconjunctivitis has not been found to be epidemic throughout the United States. The West Coast and Hawaii have reported more complications and more extensive ocular involvements than other areas. (One figure, discussion.) George H. Stine.

Cogan, D. G., Kinsey, V. E., and Drinker, P. Infrared therapy of flash keratoconjunctivitis. *Jour. Amer. Med.*

Assoc., 1943, v. 123, Dec. 4, p. 883. (See Section 16, Injuries.)

Smart, F. P., Young, C. A., and Phillips, K. The treatment of gonorrheal ophthalmia by diathermy in conjunction with sulfonamides. United States Naval Med. Bull., 1943, v. 41, Nov., pp. 1727-1730.

The authors believe that the superior efficacy of combined general fever therapy and hemotherapy over either alone in the treatment of gonorrheal ophthalmia is no longer debatable. Temperature is not the sole factor in curing these infections, for numerous cases have been cured by temperatures lower than the thermal death-point of the invading organism. Short-wave diathermy ranging from 16 to 30 meters and the ultrashort wave from 6 to 10 meters are used in the Navy. A small pancake coil or drum is employed to produce an electromagnetic field and the ultrashort wave is applied with small condenser-spaced discs. In case of necessity the applications may be given with safety every three hours during the 24-hour day. In the first case reported, long-wave diathermy was repeated every eight hours for three sessions. Sulfa drugs were not used. Improvement was noted after eight hours and recovery was complete.

In the second and third cases 15 grains of sulfathiazole was given every three hours during the 24-hour period, in combination with short-wave electromagnetic treatments lasting 30 minutes every 24 hours for approximately six treatments. Within six hours after the first application, notable subjective and objective improvement was noted. Smears were negative for gonococci after 48 hours, and complete recovery without loss of vision resulted in 12 and 18 days respectively.

Charles A. Bahn.

Sulzman, J. H., and Elliott, C. H., Jr. Powdered sulfathiazole in treatment of conjunctivitis. United States Naval Med. Bull., 1943, v. 41, Sept., pp. 1396-1399.

One hundred and sixty-seven persons (apparently domiciled in naval barracks) who had conjunctival redness from various causes were treated by the authors in two groups. Gonorrheal conjunctivitis was excepted. One hundred and thirty-three received an unstated number of instillations of unstated strengths of argyrol and zinc sulphate, and are reported to have had a seven-day average duration. Forty-four of this group were treated with conjunctival applications of powdered sulfathiazole, administered on an ear spoon and preceded by a 1-percent-potocaine instillation. These had an average duration of only two days. (In trying to understand the astoundingly decreased duration produced by the sulfathiazole powder in such a varied group of cases of conjunctival redness physically and chemically produced, the reviewer wonders how much the discomfort produced by the sulfathiazole stimulated the urge to get well by making the cure more painful than the disease.)

Torres Estrada, Antonio. Results obtained in ten years with my personal technique for the surgical treatment of pterygium. Bol. del Hosp. Oft. de Ntra. Sra. de la Luz, 1942, v. 2, Jan.-April, pp. 4-15.

This author insists upon the importance of excising the hypertrophied episcleral tissue. After separation of the head of the pterygium from the cornea, leaving Bowman's membrane perfectly clear, the head of the pterygium is excised, but without disturbing the neighboring attachments of the conjunctiva to the corneal limbus. The

author then dissects the conjunctiva from the underlying episcleral hypertrophy, and completely removes the hypertrophied episcleral tissue down to the sclera. Hemorrhage must be carefully controlled to avoid the risk of a conjunctival hematoma. A vertical cut upward in the conjunctiva and another vertical cut downward form two V-shaped conjunctival flaps, the upper one of which is carried down into the gap on the corneal side of the lower incision, so as to make an N-shaped scar the angles and lines of which are united by as many sutures as are found necessary in the particular case. Without statistical details, the author claims success in about 95 percent of 163 cases operated upon by this method since 1939. (9 illustrations.) W. H. Crisp.

CORNEA AND SCLERA

Arruga, H. Notes on corneal grafting from the cadaver. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Aug., pp. 163-166.

Arruga discusses a number of problems in connection with corneal transplantation and arrives at the following conclusions: (1) Corneas from cadavers are at least as good as those obtained from the eye enucleated from the living. (2) Although good results have been obtained from eyes preserved for four days, it is logical to expect that the earlier they are used the better the result will be. (3) Heterotransplants always result in opacification. (4) To remain clear, transplants must be placed at least in some part contiguous to relatively normal cornea if nutrition and thus transparency are to be maintained. (5) Post-operative imbibition of tears or aqueous indicates a poor prognosis for the graft. (6) In general the greater the post-operative reaction the greater the

opacification of the graft. (7) Myopia frequently results following keratoplasty. (8) Keratoplasty may be performed in inflammatory conditions as soon as the acute phase has subsided and as soon as it is certain that opacification of the cornea will result. Central corneal ulcers and infiltrations may be excised, and with transplantation the period of disability is much shortened. J. Wesley McKinney.

Bedell, A. J. Distribution of epidemic keratoconjunctivitis in the United States. *Jour. Amer. Med. Assoc.*, 1943, v. 123, Dec. 25, p. 1101. (See Section 5, Conjunctiva.)

Burch, E. P., and Gewirtz, A. J. An ocular complication following mechanical fever-therapy. *Venereal Dis. Information*, 1943, v. 24, Nov., pp. 330-331.

The frequency of superficial punctate keratitis following mechanical fever-therapy combined with sulfathiazole orally in the treatment of chronic gonorrhea led the authors to experiment with local applications of mineral oil as a preventative. In six patients receiving this general treatment, one drop of mineral oil was placed in the left eye every two hours during the eight hours of fever therapy, the right eye being untreated. Although in several cases the condition appeared in the untreated eye, it never occurred in the eye treated with mineral oil. A larger series of 25 cases was then treated with mineral oil in both eyes as above described. In none of these cases was superficial punctate keratitis observed. The authors believe with Neame that the ocular condition is essentially a virus infection which becomes active after lowering of corneal resistance by dryness and high temperature.

Charles A. Bahn.

Buschke, W., Friedenwald, J. S., and Fleischmann, W. **Studies on the mitotic activity of the corneal epithelium.** Johns Hopkins Hosp. Bull., 1943, v. 73, Sept., p. 143.

The method of obtaining, clearing, staining, and counting fragments of rat cornea to demonstrate mitotic activity of the corneal epithelium is described. Mitotic activity may shed important light on actions of drugs and processes of repair.

Standardization of mitosis counts in normal rats and then following colchicine injection indicates the rate of mitosis. This is possible because of the arrest of mitosis in the metaphase following use of the drug, without influence either on the rate of entrance into mitosis or the velocity of the cycle up to this phase. With this as a basis it was found that ether anesthesia inhibited entrance of corneal epithelial cells into mitosis, and in certain conditions altered the speed of the process.

Locally applied cocaine hydrochloride and ephedrine hydrochloride decrease the entrance of epithelial cells into mitosis. Owen C. Dickson.

Das Gupta, B. K. **Parenchymatous keratitis following riboflavin deficiency.** Indian Med. Gaz., 1943, v. 78, April, p. 198.

A partially albinotic 30-year-old Hindu male had marked deep keratitis of one eye and other local signs. Vascularization of the cornea of the affected eye was entirely absent. Total clearing of the cornea occurred in 29 days after administration of 100 mg. of lactoflavine administered both orally and intramuscularly, the average daily dose being 4 mg. Atropine locally was the only additional therapy. Clearing progressed gradually from the limbal region centrally, suggesting restoration

of the vitamin factor from the limbal circulation. Of interest is the fact that at no time was there any sign of corneal vascularization.

Rados, Andrew. Fundus lesions in syphilis. *Jour. Med. Soc. New Jersey*, 1943, v. 40, Aug., p. 304.

The pathologic picture of syphilitic lesions of the uveal tract is most commonly found in the choriocapillaris, as against sympathetic ophthalmia in which the deep layers are affected. Pigment epithelium and outer retina are secondarily affected, justifying as more correct the designation of chorioretinitis.

Congenital chorioretinitis, or the typical salt-and-pepper fundus of luetic origin, is about the only characteristic syphilitic lesion. A syphilitic basis for many fundus pictures is assumed from other clinical findings. Vascular pathology due to Buerger's disease, or lesions of Boeck's sarcoid and undulant fever, may require reclassification of signs hitherto described as luetic.

Four types of fundus change in congenital syphilis are described. First,

the bilateral, posterior polar or peripheral, delicate yellowish-red dots mixed with tiny pigment spots of the salt-and-pepper type which are nonprogressive. These may occur independently or in association with the other more frequent forms. Types two and four consist of patches of yellowish red occurring in the extreme periphery and measuring about one-half disc diameter. Pigmentary changes are late, and lesions may be unilateral. The severe form of type two may be hard to differentiate from retinitis pigmentosa. In type three the patches are of lighter color and the pigmentation less marked. This type may occur unilaterally and changes progress from the extreme periphery toward the center. Pigmentation may increase in the late stages, giving a picture similar to that of type two and of which perhaps it is merely one modification.

Acquired syphilitic lesions occurring usually in the second stage are described. Emphasis is placed on vitreous exudation, hazy fundus, frequent bilaterality, and the end picture of small, pigment-ringed central lesions progressing to larger areas at the periphery.

Wienman, G. J. Sympathetic ophthalmitis. *United States Naval Med. Bull.*, 1943, v. 41, Sept., pp. 1392-1396.

The author believes that at least 17.5 percent of all badly injured eyes, if not removed, will lead to sympathetic ophthalmitis. Enucleation should be performed within two weeks of the ocular injury, as the most dangerous period is between the third week and the third month. The prognosis in advanced cases is poor, and the only good treatment is prophylactic enucleation. Sulfanilamide and foreign-protein therapy appear to be of value, but continued cycloplegia is the greatest single factor in the treatment. There is a great tendency for sympathetic ophthalmitis to undergo remissions and exacerbations. No case can be considered quiescent until at least one year has elapsed. The author reviews four cases of sympathetic ophthalmia seen in civilian practice. The first received a knife wound of the uveal tract, and developed sympathetic ophthalmitis in the second eye after approximately six weeks. Notwithstanding enucleation after the second eye became involved, total blindness resulted. In the second case, the condition followed removal of a lens which had been dislocated when the eye was struck by a baseball. Sympathetic ophthalmitis developed after approximately six weeks, the offending eye being removed at that time. Sulfathiazole, foreign protein, and calcium glucinate intravenously, were administered; the corrected vision ultimately being 20/20. On several occasions during one year, the condition recurred following the discontinuance of sulfanilamide. In the third patient, the manifestation of sympathetic ophthalmitis was an optic neuritis, following a subconjunctival scleral rupture, and involving essentially only the posterior segment of the second eye. In the fourth case, total blindness resulted

largely through the patient's lack of cooperation.

Yanamura, H. Y., and Green, R. G. Intraocular virus infections. *Science*, 1943, v. 98, July 9, p. 45.

The authors have succeeded in experimentally transmitting the virus of epizootic fox encephalitis by inoculating the virus into the anterior chambers of eyes of dogs, wolves, and foxes. The application of their technique has aided materially the study of this virus infection, because it results in 100 percent of infections which can be followed by gross observation and can be verified by demonstration of inclusion bodies in stained preparations of the corneal endothelium. The clear-cut results have increased knowledge concerning the spines of animals susceptible to fox-encephalitis virus, and open possible avenues of investigation of other viruses which at present can be demonstrated only with difficulty.

8

GLAUCOMA AND OCULAR TENSION

Fralick, F. B., Cooper, J. H., and Armstrong, R. C. Uveitis with secondary glaucoma. *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1942, 4th mtg., Nov.-Dec., pp. 92-99.

Secondary glaucoma in cases of iridocyclitis occurred in 22 percent of 1,282 eyes examined. Medical therapy consisting of mydriatics or miotics or their combination in addition to heat, salicylates, foreign protein, and removal of focal or general infection resulted in normalization of the intraocular tension in 30 percent of the eyes. Paracentesis resulted in normal tension in 43 percent of the eyes when

used in active iridocyclitis accompanied by glaucoma. If paracentesis is going to be successful one or two paracenteses at the most are usually sufficient, and after failure of paracentesis on two occasions some other procedure may better be utilized unless the eye shows active inflammatory changes contraindicating other surgery. Of all operative procedures, iridectomy gave the highest percentage (71) of controlled intraocular tension in iritic glaucoma. If the ocular inflammation is first decreased to a minimum, favorable reduction in tension by iridectomy is enhanced. Corneoscleral trephining was successful in reducing elevated intraocular tension in 60 percent after the iridocyclitis became quiescent. This operation is not indicated in eyes showing active uveitis. Cyclodialysis, iridencleisis, transfixation of the iris, and combined extraction of complicated cataract in quiescent iridocyclitis with secondary glaucoma, resulted collectively in reducing the tension to normal in 62 percent of the eyes operated upon. Sixty-seven (25 percent) of the eyes showing glaucoma after development of primary iridocyclitis were primarily or finally enucleated. (9 tables.)

Gertrude S. Hausmann.

Gradle, H. S., and McGarry, H. I. *Why a glaucoma clinic?* Trans. Amer. Acad. Ophth. and Otolaryng., 1942, 47th mtg., Nov.-Dec., pp. 100-105.

The value of the glaucoma clinic is mainly that 95 percent of the people afflicted with glaucoma are kept under observation for two years or more, whereas previously 96 percent of them disappeared within two years. Analysis of the first 283 eyes with primary glaucoma observed over a period of two years shows that the better the visual

acuity and the visual fields are at the time of the discovery of the disease the better is the chance of preservation of useful vision by continued observation and treatment. Of all the eyes with useful vision, only 14 percent became practically blind within two years. Loss of vision in the peripheral field usually precedes loss of central visual acuity. (4 tables, discussion.)

Gertrude S. Hausmann.

La Motte, W. O. *Primary glaucoma, its etiology, symptoms, and diagnosis.* Delaware State Med. Jour., 1943, v. 15, June, p. 101.

This paper presents a brief survey of glaucoma, intended for a nonophthalmologic medical group. Various reports of the incidence of blindness due to glaucoma range up to 20 percent. A classification of glaucoma is presented, primary glaucoma being divided into acute inflammatory, chronic inflammatory, and chronic simple types.

The early signs and symptoms of each of the three types are described, emphasizing differentiation from conjunctivitis and acute iritis. The early transient symptoms are described, along with cautious provocative tests for early cases. The importance of visual-field studies is brought out, and an illustrative case is cited.

Benjamin Milder.

Lloyd, R. I. *Glaucoma and the general practitioner.* New Orleans Med. and Surg. Jour., 1943, v. 96, Aug., p. 67.

The author summarizes the mechanism by which increased intraocular pressure impairs visual acuity and the field of vision. Briefly, in nontechnical language, the author outlines the signs and symptoms of glaucoma, the methods of diagnosis, and the responsibility

of the general practitioner in education of the public and control of glaucoma.
Benjamin Milder.

McLean, J. M. What everyone should know about glaucoma. *Sight-Saving Review*, 1943, v. 13, no. 2, p. 83.

In simple readable style the article tells the public of the importance of glaucoma, its symptoms, and its control. The author advises all who are middle-aged or older to find out if they have the condition.

Robert N. Shaffer.

Moreu, Angel. The vascular factor in the treatment of glaucoma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Sept., pp. 272-281.

This report is based on gonioscopic observation of one hundred cases of various types of primary glaucoma. In all hypertensive eyes an edema of the ciliary body and of the root of the iris was observed, manifested by a dark-bluish coloration and fine spots of exudation. This was interpreted to be an edema due to venous congestion rather than inflammatory edema. Successful operation or medical treatment caused disappearance of the edema but, if the tension was not completely normalized or if loss of vision and field continued despite normalization of tension, the edema persisted. All of the patients were stated to have either hypertension, arteriosclerosis, circulatory disturbance, or disequilibrium of the sympathetic-parasympathetic nervous system. Glaucoma was found to be in large part caused by a circulatory disturbance which was both local and general.

The classical medical and surgical treatment of glaucoma was employed with the addition of a vasodilator drug

"Lacranol." This is a sodium nucleotide extracted from the muscles and blood of warm-blooded animals. Taken by mouth it produces capillary dilatation without affecting appreciably the arterial pressure or intestinal musculature.
J. Wesley McKinney.

Torres, Estrada A. Modifications of Heine's cyclodialysis. *Jour. Internat. College of Surg.*, 1943, v. 6, July-Aug., p. 378.

The modification consists in making the scleral opening only 4 to 5 mm. wide and placed at the 8 o'clock position in the right eye and at 4 o'clock in the left. A special spatula, set at an angle of 145° with the shaft, is introduced and the ciliary body is separated from the sclera for 180°. Both eyes are operated upon at a single session. The procedure is simple, involves no danger to sight, and is especially recommended in advanced glaucoma. The authors consider that cyclodialysis with ample separation is the only operation indicated for glaucoma. (2 figures.)

9

CRYSTALLINE LENS

Bellows, J. G., and Nelson, D. Anoxia cataract. *Proc. Soc. Exper. Biol. and Med.*, 1943, v. 54, Oct., p. 126.

Rats were placed in a steel chamber in which the pressure was gradually reduced to an equivalent of 30,000 feet or more altitude. Fifty percent of the rats died. Seventy-five percent of the dead animals and 10 percent of the survivors showed lens opacities. To prove that anoxia alone is the important factor in producing cataract and that pressure and asphyxia are unimportant, rats were placed in a glass

chamber through which a mixture of 5 percent oxygen and 95 percent nitrogen was constantly flowing, the rats developing cataract under these conditions.

Since lactic acid plays a great role in the oxidation process of the lens, the lactic-acid content of the aqueous at high altitudes was determined. The aqueous humor of one eye in each animal was removed. After two hours for recovery the animals were placed in a decompression chamber, some being kept for control. The lactic-acid content of the aqueous of the second eye was three to four times as high as that of the first eye or of the controls. The pH of the aqueous was found unaltered in high altitude.

After decompression the iris is hyperemic. In the superficial cortex diffuse gray opacities are visible. The anterior superficial suture becomes more readily visible. Similar although less marked changes are found in the posterior cortex. In severe cases the fiber structure is lost and a glistening white total cataract is formed. After an hour the cataract gradually regresses.

The authors examined the lenses of human volunteers subjected to decompression equivalent to 18,000 feet altitude, but no lens opacities were noted.

R. Grunfeld.

Berkove, A. B. Asthenopia and amblyopia caused by congenital lens-vitreous changes. *The Military Surgeon*, 1943, v. 93, Nov., p. 415.

The author describes a symptom complex characterized by defective vision and painful, light-sensitive eyes. Slitlamp studies reveal mutton-fat opacities scattered throughout the lens, sclerotic posterior Y, and coarse lamellar structure in the vitreous. The writer

reports five cases as examples of 25 cases studied. It is suggested that the condition is frequent in cases of unexplained amblyopia.

Robert N. Shaffer.

Buschke, Wilhelm. Classification of experimental cataracts in the rat. *Arch. of Ophth.*, 1943, v. 30, Dec., pp. 735-750.

Cataract formation has been observed in the rat under a number of different conditions. It has been found that feeding the rat a diet deficient in tryptophane produces either an acute or chronic form of cataract, whereas addition of tryptophane to the diet causes arrest in cataract formation. Microchemical studies show that there is never a complete loss of bound indole from the lens even in the advanced stages of tryptophane-deficiency cataract. Such cataracts are associated with inhibition of body growth and alterations in other epithelial structures, namely cornea, hair, and testicular epithelium. Attention is called to the fact that lens, hair, and testicle are all epithelial tissues that continue to grow throughout life. Cataracts resulting in rats from thallium poisoning and from riboflavine deficiency are also associated with similar changes in cornea, hair and testicular epithelium.

On the basis of morphology, development, and allied symptoms, a classification of experimental cataracts in rats includes three principal groups, the diabetic, the tetanic, and the dystrophic. The diabetic group includes cataract associated with experimental diabetes as well as galactose and xylose cataracts; the tetanic group includes cataracts occurring in the course of dietary and postoperative tetany; and the dystrophic group, the cataracts ac-

companying riboflavine deficiency, chronic thallium poisoning, and tryptophane deficiency. The article is illustrated by slitlamp drawings of the various types of lens changes. (11 figures, references.) John C. Long.

Buschke, Wilhelm. Dystrophic cataracts and their relation to other "metabolic" cataracts. *Arch. of Ophth.*, 1943, v. 30, Dec., pp. 751-762.

The author divides both experimental and clinical "metabolic" cataracts into hyperglycemic, tetanic and dystrophic groups. The dystrophic group is discussed in some detail and is subdivided in the following classification: (A) Experimental conditions: 1, riboflavine deficiency; 2, experimental chronic thallium poisoning; 3, experimental tryptophane deficiency. (B) Clinical cataract syndromes with predominantly atrophic dermatoses: 1, Rothmund syndrome; 2, Werner syndrome. (C) Cataract syndrome, with dermatoses of the atopic dermatitis type: Andogsky syndrome. (D) Clinical cataract syndromes associated with other cutaneous conditions, including those associated with follicular keratosis, telangiectasis, or myxedema, or with anomalies of the hair. (E) Cataract associated with mongolism and with myotonic dystrophy.

Typically the dystrophic cataracts are associated with alterations in other structures of the body. Primary endocrine dysfunction does not effectively explain the occurrence of these cataracts. The author concludes that the lesions are probably due to primary metabolic disturbances in the affected tissues on a hereditary basis. (Bibliography.) John C. Long.

The advantages of drawing as a means of training the fingers for cataract surgery are emphasized. Medical students should have to pass an examination in drawing.

The most important preparation of the patient is psychologic. He should come to operation free from fear and confident of a successful outcome of his operation. The simpler the physical preparation is, the better. The patient must be examined for foci of infection, especially the teeth. The lacrimal sacs should be irrigated a few days before the operation, not on the day before. A culture should be taken 48 hours prior to operation, for medico-legal reasons if for no other. The tears contain their own antiseptic, and washing with normal saline just before operation is the author's only local treatment.

The only general treatment is to have the bowels properly emptied. If a preliminary iridectomy is to be done, eserine must be used with the cocaine because it is difficult to perform a neat iridectomy on a dilated pupil. No preliminary narcotics are used.

The advantages of a preliminary iridectomy are these: It gives the surgeon an indication of how the patient will behave at extraction and the size of the lens can be estimated in the coloboma. The cataract section is much easier to make when there is no danger of wounding the iris. For the preliminary iridectomy, a keratome incision is used and an iris hook is substituted for forceps. The patient goes home on the fourth day if there is no infection.

Extraction is done a month after the preliminary iridectomy. The author uses a projection lamp to avoid reflections. A nurse holds one of the patient's hands centrally over the chest. Then the patient is not asked to look down, but to look at his hand.

Butler, T. H. Cataract extraction. *Brit. Jour. Ophth.*, 1943, v. 27, Nov., pp. 495-509.

For akinesia an injection of novocaine and adrenalin into both lids and into the temple is used half an hour before operation. No retrobulbar injection is used.

The section is made with a speculum in place. The speculum is removed after the section. Visible cortex is expressed with a lens spoon. No attempt is made to wash out cortex. If vitreous is lost, the eye is closed at once and is not opened for four days. If the iris is then impacted, it can be dealt with under a general anesthetic.

If capsulotomy of aftercataract is necessary it should be done within a month after operation if the eye is free from inflammation. At this time, the zonule is still maintaining some tension upon the capsule, and if a vertical incision is made the slit gapes and gives an oval aperture. The Ziegler knife should not be introduced through the clear cornea but through the limbus.

Alternative types of extraction are considered. Simple extraction with a round pupil is objectionable because of the amount of pressure on the globe which is necessary and the trauma to the iris. Extraction under a conjunctival bridge makes it difficult to deliver the lens and there is often an extreme degree of astigmatism. The author considers the intracapsular operation far more dangerous than any other type because of the heavy pressure he has found necessary to deliver the lens. He has performed very few such operations and will never do any more!

Edna M. Reynolds.

Gemeroy, J. C. Intracapsular cataract extraction. *Michigan State Med. Soc. Jour.*, 1943, v. 42, Oct., p. 812.

The author describes a modification of Dimitry's suction syringe wherein it is possible to release the plunger—

to create the vacuum at the instrument tip—while still holding the syringe near its base with thumb and fingers. Its application in 56 cases is reported. In six of these there had been failure to remove the lens by other intracapsular methods. Suction was applied at the upper anterior portion of the capsule and the lens slid out rather than tumbled. Thirty-five of fifty cases required iridectomy, while in 15 dilatation of the pupil was sufficient to allow retention of a round pupil.

The difficulties encountered with this method are illustrated by a case in which the zonule failed to rupture in a 17-year-old diabetic, rupture of the lens capsule after applying suction, in four cases of hypermature cataract, and one case of rupture of the capsule on introducing the tip. Prolapse of the iris occurred in two cases and retinal detachment in three of the 56 cases. Vitreous was lost in seven cases but not as a result of its being sucked into the syringe. This method does not supplant others but affords a help which may be valuable, as demonstrated in six of the author's complicated cases.

Goldsmith, Jacob. Original studies on the internal dynamics of the intracapsular cataract extraction. *New York State Jour. Med.*, 1943, v. 43, Sept. 15, pp. 1739-1750. (See *Amer. Jour. Ophth.*, 1943, v. 26, June, p. 640.)

Howell, T. J. A plea for the intracapsular extraction of cataract. *South African Med. Jour.*, 1943, v. 17, Sept. 11, p. 275.

Essential requisites for a successful intracapsular extraction in the hands of the author are briefly described. These include lid akinesia, a slowly administered retrobulbar injection, and

superior rectus and corneal sutures. A fairly large limbal section made the best start. Next came a small peripheral iridectomy or iridotomy in a pupil moderately dilated (not by atropine). After breaking the zonule and rotating the lens, with the latter fixed in the wound, the capsule forceps were released and reapplied, and the lens was delivered by lateral rotatory pulling movements. Eserine 0.5 percent and cocaine 2 percent in oil were instilled into the conjunctival sac.

Elimination of the possibility of glaucoma or delayed union from incarcerated capsule, avoidance of capsulotomy after the extraction, and the perfect cosmetic result obtained from a successful intracapsular extraction far outweigh the very limited disadvantages of the operation.

McDannald, C. E. Neurodermatitis with cataract. *Arch. of Ophth.*, 1943, v. 30, Dec., pp. 767-769.

Two cases of neurodermatitis with cataract were observed in white patients, one a man of 18 and the other a woman of 23 years. Both patients were emotionally unstable and reacted positively to many different tests for allergy. The skin of the eyelids was brawny, red, and itchy in each case. In each patient, cataract appeared and matured rapidly during the active stage

of eczema and neurodermatitis. Linear cataract-extractions were performed with good results on all four eyes involved. The woman failed to get normal vision because of a coexisting bilateral keratoconus. Apparently cataracts associated with neurodermatitis lend themselves well to surgical intervention. (References.) John C. Long.

Marback, H. Sign of oil drop in pupil; microphakia; anterior lenticonus. *Arquivos Brasileiros de Oft.*, 1943, v. 6, Aug., pp. 119-124.

A man aged 23 years came to the clinic on account of poor vision which had existed since infancy. The pupils reacted well to light, and had an average diameter of 2 mm. The skiascopic examination indicated myopia of 30 diopters. Under atropine each eye showed a brilliant circle coinciding exactly with the equator of an abnormally small lens, the lens diameter appearing to be approximately 4 to 5 mm. There were two distinct pupillary zones, one inner, central, opalescent, the other peripheral but clear, the whole picture giving the appearance classically described as "oil drop in the pupil." Ophthalmoscopy showed in each eye two images of the ocular background, one central and direct, the other peripheral and inverse. The sudden interruption at the boundary between the two images made it impossible to follow the course of the retinal vessels.

Biomicroscopy indicated a spherical deformity of the anterior face of the lens, with anterior chamber very shallow, the anterior pole of the lens being hardly 2 mm. behind the cornea. The deformity appeared to exist at the expense of the anterior capsule and the anterior half of the senile nucleus, the fetal nucleus having a normal aspect. The zonula was visible in the whole

circumference, but there was a reduced number of suspensory fibers. The lens was not dislocated. (Illustrations, references.) W. H. Crisp.

Neblett, H. C. Ulcer of the cornea at the site of the corneal-suture wound. *Southern Med. and Surg.*, 1943, v. 105, Oct., p. 452.

Cataract extraction was performed on two negro women, one aged 67 and the other 70 years. Each gave the history of having had multiple chalazion of the lids of each eye over a period of years. On the fifth and seventh day respectively after the operation the eyelids became indurated and an ulcer developed at the site of the suture wound. The ulcer was round and had no tendency to undermine. In one case recovery was had with fair vision; in the other, which was complicated by severe and protracted uveitis, light perception only was secured. The author concludes that corneoscleral sutures are contraindicated in any case presenting a history of a chronic inflammation of the lids, of the lacrimal apparatus, or of the globe.

Stone, L. S. Factors controlling lens regeneration from the dorsal iris in the adult *Triturus viridescens* eye. *Proc. Soc. Exper. Biol. and Med.*, 1943, v. 54, Oct., p. 102.

Slight injuries to the fully developed lens in the adult salamander eye cause the lens to degenerate, and in such cases a new lens develops from the dorsal pupillary margin of the iris. If a piece of a dorsal iris from a normal eye is transplanted to a lenssectomized host eye a new lens will develop from the graft. If, however, the host eye possesses a normal lens the latter strongly inhibits lens regeneration. Ex-

periments proved, moreover, that the presence of a regenerating lens from an iris not older than 25 days in a lenssectomized eye does not inhibit nor prevent the regeneration of a lens from other dorsal iris-tissue in its environment, and under some circumstances even three lenses may grow in the same eye. If the regenerating-lens is older than 25 days it inhibits lens regeneration from another iris tissue.

Torres Estrada, A. Surgical procedure in the operation of cataract. *Jour. Internat. College of Surg.*, 1943, v. 6, July-Aug., p. 301.

Torres Estrada considers akinesia of the lids and wound sutures the most important details of technique. He employs two corneoscleral sutures, one at the ten o'clock and one at the two o'clock position, leaving a conjunctival bridge above. A small inverted-V-shaped cut in the conjunctiva at the 12 o'clock position permits performance of a peripheral iridectomy, the cut being afterward sutured. The lens is extracted with an erisiphake or with capsule forceps. (8 figures.)

Eugene M. Blake.

Wolfe, O. I., and Wolfe, R. M. The Barraquer technique in incipient cataract and glaucoma. *Jour. Internat. Col. Surg.*, 1943, v. 6, July-Aug., p. 354.

The authors feel that intracapsular extraction is the procedure of choice in cataract occurring in or with incipient glaucoma. They prefer a modification of the Barraquer erisiphake technique with the addition of a punch sclerectomy. The incision is made with a keratome 1.5 mm. above the limbus, and is enlarged with scissors. Two corneoscleral sutures are placed before the section is made, and several con-

junctival sutures at the end of the operation. Details as to the amount of suction vacuum employed are given and stress is laid upon a careful general preoperative study of the patient. (6 figures.)

RETINA AND VITREOUS

Arruga, H. Search for and localization of retinal tears. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Aug., pp. 173-180.

The importance of exact localization of tears before and during the operation for retinal detachment is emphasized. Not only must the tear be sealed but the less the amount of diathermy used the less will be the postoperative reaction and the greater will be the probability of success. With the modern technique, reattachment should be obtained in 70 to 80 percent of the cases operated upon. The various methods of localizing tears are reviewed.

J. Wesley McKinney.

Ballantyne, A. J. **Retinal hemorrhage.** *Irish Jour. Med. Science*, 1943, sixth series, Oct., p. 551.

A sudden rise of pressure in the venous circulation as it occurs in thrombosis, choked disc, or subarachnoidal hemorrhage will result in venous stasis with consequent hemorrhage in the retina. But the distribution of the hemorrhage will differ in the three conditions mentioned.

Although in thrombosis of the central retinal vein the hemorrhage may be sudden, it is nevertheless only the final phase of a progressive, gradually developing obstruction of the venous circulation. The walls of the veins covering a wide area have suffered for a long time from the consequent anox-

emia, and the hemorrhage, therefore, will be widespread. In papilledema and subarachnoid hemorrhage, however, the retinal hemorrhage takes place near the disc, where the surrounding tissues give diminished support to the venous wall. Furthermore, the hemorrhages often form a sleeve or cuff on the veins as they leave the disc.

Capillary hemorrhage predominates when the hemorrhage is seen between the visible retinal vessels. If a blood vessel passes through such a hemorrhage it is accompanied by a blood-free zone, a pale band on either side of the blood column, corresponding to the capillary-free zone which lies on either side of the retinal arteries.

Of arterial origin are the striate and fan-shaped hemorrhages lying in the nerve-fiber layer where the first capillary plexus is situated. Of venous origin are the punctate or petechial hemorrhages which take their origin from the efferent venules forming the deepest capillary plexus in the outer molecular layer. From these the arterial aneurysms have to be differentiated. The latter are round, blood-red masses whose diameter is about that of a secondary retinal vein, and which have a glistening reflex at their center giving the impression that they are encapsulated.

Punctate hemorrhages do not show a surface reflex, and when they occur in the perimacular region they are pathognomonic of diabetes mellitus. In retinitis circinata the hemorrhage has a petechial character, while in disciform degeneration the preceding hemorrhage consists of an ill-defined splotch.

Esteban, Mario. So-called "black vision" and "red vision" of aviators. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Sept., pp. 251-268.

Studies of the effects of centrifugal force on the human body have been stimulated by the importance of aviation in modern warfare. In dive-bombing and the normal "loop" the head remains inside and the feet outside in relation to the curvilinear movement of the airplane. The displacement of the blood is directed away from the head to the abdomen and lower extremities, causing ischemia of the head. The retinal circulation is particularly susceptible to the exsanguinating effect of centrifugal force acting in the above manner, and gives the first danger signal before other symptoms develop. Forms and colors disappear. A black veil falls before the eyes, giving rise to the phenomenon of "black vision." Then, if the action of centrifugal force is more marked, total loss of consciousness occurs. The effect last only momentarily, as the pilot comes out of the turn with consequent lessening of the centrifugal force.

More dangerous than the above are the outside loops in which the feet and abdomen occupy the inside position and the head the outside. The blood and cerebrospinal fluid are displaced toward the head, with consequent increase in intracranial and intraocular pressure. The pilot experiences a fullness of the

head which may suddenly become a headache, followed by a blackout. The loss of consciousness lasts only momentarily, but the headache often persists several hours. Often ecchymoses of the conjunctiva, eyelids, and cheeks are produced, and there is a real danger of cerebral hemorrhage. In the case of outside loops retinal circulation is protected by the increased intraocular pressure, and retinal hemorrhages are rare. J. Wesley McKinney.

Knapp, Arnold. Retinal detachment and trauma. *Arch. of Ophth.*, 1943, v. 30, Dec., pp. 770-774; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41.

As it is not yet exactly known how a detachment of the retina is produced, the relation to trauma must remain vague. The author studied four hundred cases of detachment, obtaining in 52 a definite history of trauma. Traumatic origin of detachment is obvious in cases in which there has been a puncture wound or direct trauma to the eye. The cause of detachment where there has been indirect trauma is much more obscure. Detachment is often associated with injuries involving generalized jarring or lifting, or with coughing or sneezing. It is assumed that many detachments follow indirect injuries in eyes already predisposed to detachment. Among predisposing factors may be considered myopia, cystoid degeneration of the retina, degeneration due to local circulatory disturbances, and changes in the vitreous. Predisposition to detachment is evidenced by the fact that of the cases here reviewed, 14 percent showed bilateral involvement.

Detachment of the retina was observed in 37 cases of aphakia. Predisposition and loss of vitreous are thought to be factors in this complica-

tion. Detachment has been frequently observed after needling and either extracapsular or intracapsular extraction. Operation for congenital cataract seems to have an especially bad prognosis. This may be because of the greater length of life after the operation. In a series reported by Shapland, the detachment occurred at an average interval of 24.6 years after removal of congenital cataract. (References.)

Lijo Pavia, J. The central artery of the retina. Provocative pulsation. Its analysis by photography. (Part 1.) *Rev. Oto-Neuro-Oft.*, 1942, v. 17, May-June, pp. 79-85. (See also paper by Lijo Pavia and Cerboni.)

The author uses an ophthalmodynamometer for making pressure on the eyeball to produce the arterial pulse, photographs of the fundus then being made for corroboration and study. As in a previous paper, he finds that the appearance, under pressure, of the arterial pulse represents the minimal arterial pressure. He gives due credit to Bailliart's observations.

In his own observations of three cases (his fundus photographs are well done in progressive frames), the dynamometer is used to gradually increase the pressure made upon the eyeball to the point of arterial collapse or contraction during diastole (known as the median pressure). He discovered that in hypertensive patients this phase of arterial contraction was more prolonged than in normal individuals, and he interpreted this as a latent state of

angiospasm. Further reports on this subject are to follow.

Edward Saskin.

Lijo Pavia, J., and Cerboni, F. C. The central vessels. Double retinal pulse. Photograph evidence. (Part 1.) *Rev. Oto-Neuro-Oft.*, 1942, v. 17, March-April, pp. 47-51.

The authors state that the spontaneous and evident retinal venous pulsation depends on the equilibrium established between the pressure of the retinal veins and the intraocular pressure, the former being dependent upon the power of the cardiac contractions. Evidence is offered to the effect that the venous pulse is present in only 37 percent of all individuals.

Applying an ophthalmodynamometer to the eye it is found that the venous pulse is a manifestation of the ventricular systole. Continued pressure on the eyeball causes disappearance of the venous pulse at the time of auricular systole, by reason of neutralization of the maximum intravenous pressure. Further compression of the eyeball now causes appearance of an arterial pulsation, indicating the minimal arterial pressure, and normally no visible venous pulse. However, in certain cases, the venous pulsation persists in spite of pressure on the eye with the dynamometer, the phenomenon known as a "double retinal pulse." The authors feel that persistence of the venous pulse under pressure on the eye is due to poor return circulation which causes a rise in the venous pressure almost to the level of the arterial pressure. In a case of central retinal-vein closure here reported, the dynamometer revealed a double retinal pulse. The authors' findings are substantiated with a fundus photograph.

Loewenstein, A., and McGregor, I. S. Senile and other pigmentary changes in the retinal ganglion cells. *Brit. Jour. Ophth.*, 1943, v. 27, Nov., pp. 486-495.

To determine whether the basis for staining of ganglion cells with scarlet red in hypertensive and diabetic retinopathy was just a senile change or was really pathologic, an investigation of fatty changes in the ganglion cells in normal eyes of different age-groups and in various diseased conditions was undertaken.

The ganglion cells of the middle-aged and aged show fatty droplets of lipid staining in the plasma. In children, these changes are absent for the most part, but they do occur. The droplets may be so small as to be scarcely discernible, or so gross that the whole plasma may be full of them. The large ganglion cells of the periphery suffer predominantly. The smaller central ganglion cells are much less affected or not at all.

Apart from the brilliant droplet staining of the ganglion cells with scarlet red, the plasma of the ganglion cells of the periphery in senile retinas stained with scarlet red had frequently a brownish appearance, due to the presence of diffuse brown pigment, which may be a precursor of lipid. Diseases such as hypertension, diabetes, and glaucoma cause pigmentary changes in the retinas of younger people similar to the changes seen in senile retinas. (11 illustrations, references.)

Gifford, S. R. Plastic shell for use in the simple evisceration of the globe. Arch. of Ophth., 1943, v. 30, Dec., pp. 775-776.

The only disadvantage noted in simple evisceration of the globe by the method of Harold Gifford has been the occurrence of conjunctival chemosis. As the conjunctiva is not cut during this operation, a very considerable amount of fluid may accumulate under it. The author has devised a plastic shell which can be fitted over the evisceration stump so that constant and uniform pressure is applied. This not only prevents chemosis but by holding the cornea and sclera in correct position produces a better stump. Employment of the shell is also of advantage after enucleation with implant in Tenon's capsule. (One illustration.)

Lloyd, R. I. Embryological basis of extrapapillary coloboma and conus. Trans., Amer. Acad. Ophth. and Otolaryng., 1942, 47th mtg., Sept.-Oct., pp. 7-16.

There are two types of developmental error of the human eye connected with the pigment layer, the lamina vitrea, and the choriocapillaris. These are extrapapillary coloboma, and the defects located in and about the optic nerve and known as conus, coloboma, or ectasia. Extrapapillary coloboma is named to distinguish it from defects due to defective closure of the optic fissure. These characteristic lesions are located in and about the posterior pole, are multiple or single, of

variable size and unilateral or bilateral. Histologic examination of the affected area shows only the inner retinal layer in the affected areas. The pigment layer is missing and the choroid consists only of a few shreds of pigmented tissue. The sclera may be reduced to a thin layer which may bulge, producing the change in level seen in the more serious defects. Important is the differential diagnosis of these lesions from chorioretinal tuberculosis, hereditary macular degeneration, and the results of trauma with hemorrhage. (14 illustrations.)

Smelser, G. K. Water and fat content of orbital tissues of guinea pigs with experimental exophthalmos produced by extracts of the anterior pituitary gland. Amer. Jour. of Physiology, 1943, v. 140, Dec., pp. 308-315.

The author's experiments on animals show that when an extract of anterior pituitary gland is injected into thyrectomized guinea pigs these become affected by exophthalmos with hypertrophy of the retrobulbar fat and extraocular muscles. This effect is due mostly to increase in the amount of interstitial water in these tissues but in part to increase of connective tissue in the orbital fat. The extract used was prepared from the anterior lobe of beef pituitary gland, and 15 to 20 mg. was

injected subcutaneously daily for 60 to 70 days. The animals had been thyrectomized 10 to 20 days prior to the first injection. The methods of the experiments are given in detail and the results on orbital and nonorbital tissues are shown in tabulation form. Table 1 shows a comparison of water and lipid content of the orbital tissues of control and exophthalmic guinea-pigs, and table 2 a comparison of water content of non-orbital tissues of control and exophthalmic guinea-pigs. A discussion on the result closes the article, with the statement that the cause of the increase in water content is the same in both fat and muscle and that an increased vascular permeability may possibly be the factor immediately responsible for this change. The finding that the water content of nonorbital tissues is also increased may be correlated with clinical observations of localized edema in non-orbital tissues of persons with exophthalmos.

Stone, L. S. Return of vision in transplanted adult salamander eyes after several days of refrigeration. *Proc. Soc. Exper. Biol. and Med.*, 1943, v. 54, Oct., p. 44.

Fifty-nine adult *triturus viridescens* eyes were refrigerated in sterile Ringer's solution at temperatures varying from 0 to 8 degrees centigrade, and for periods varying from 2 to 14 days and were then transplanted into freshly denuded orbits of new hosts. The best results were achieved when the eyes were preserved at between 4 and 6 degrees centigrade and for not longer than three days, the eyes in some cases recovering vision at the end of three months. If the eyes were kept on refrigeration for a longer period than three days or the temperature was

higher or lower than the optimum given above, the results were correspondingly poorer.

EYELIDS AND LACRIMAL APPARATUS

Belmonte Gonzáles, Nicolas. Totipotential operation without sectioning the internal palpebral ligament. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Aug., pp. 167-172.

The operation differs from the original in that the incision begins at the level of the internal palpebral ligament and extends rather farther downward, and the ligament is not cut. Although this modification makes the operation somewhat more difficult, the canaliculi are more surely left intact and the muscular action of the orbicularis, which propels the tears into the sac, is preserved. J. Wesley McKinney.

Sugar, H. S. Tarsconjunctival sliding-graft techniques for eyelid reconstruction. *Amer. Jour. Ophth.*, 1944, v. 27, Feb., pp. 109-123. (13 figures, references.)

Thygeson, Phillips. Staphylococcal blepharitis. *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1942, 46th mtg., July-Aug., pp. 265-272.

In a series of 249 cases, pathogenic staphylococci were found to be an important primary cause of marginal blepharitis. Increased activity of the sebaceous glands of the lids or the meibomian glands seemed also to be a very important causative agent. Staphylococcal blepharoconjunctivitis is characterized by extreme chronicity and by resistance to treatment of corneal complications and internal and external hordeola. Specific antistaphylococcal therapy consisting of staphylococcus toxoid, and local application

of sulfathiazole in ointment form, proved more effective than other methods in producing permanent healing. In only a small percentage of cases was rapid healing obtained, most cases requiring prolonged treatment. Important supplemental treatment included expression of secretion from meibomian glands and epilation of infected cilia. Gertrude S. Hausmann.

15

TUMORS

McBean, G. M. Bilateral metastatic carcinoma of choroid. *Arch. of Ophth.*, 1943, v. 30, Dec., p. 776.

A woman aged 52 years had had both breasts amputated for carcinoma. There was recurrence about the right clavicle. The right eye developed an area of episcleritis temporally and a pale gray zone was observed in the fundus under the insertion of the lateral rectus muscle. Glaucoma appeared and failed to respond to an iridectomy. The eye was removed and on microscopic examination was found to have a metastatic carcinoma under the insertion of the external rectus muscle. Numerous other metastases developed, and the left eye became blind from a wide retinal detachment which covered a solid growth. Although post-mortem examination of the eye was not permitted, it was assumed that the left eye was also the site of a metastatic growth.

INJURIES

Arruga, H. Radiographic localization of ocular foreign bodies. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Sept., pp. 282-285.

The author reviews the known methods of localization of intraocular foreign bodies and proposes a simple and

effective method of his own. The procedure consists in inserting small suture needles with attached threads into the episcleral tissue in the approximate region of the foreign body as indicated by the wound of entrance and by posterior-anterior and lateral X rays. When the needles have been inserted the X rays are repeated, giving an exact localization in relation to the needles.

J. Wesley McKinney.

Carlisle, J. M. Medical first aid in eye accidents and injuries. *Sight-Saving Review*, 1943, v. 13, no. 2, p. 75.

The author summarizes methods of first-aid treatment. He points out that usually only a physician should do more than the most superficial of treating. Various neutralizers for chemical burns are listed, together with suggestions as to follow-up care, stressing the late dangers from alkali burns, and care needed to avoid symblepharon in any of them.

Methods of handling superficial foreign bodies are given. It is suggested that all cases of penetrating foreign body and all but the most superficial corneal abrasions be sent immediately to an eye specialist. Proper early treatment can minimize or prevent permanent disabilities. All but the most trivial cases should be promptly referred to an ophthalmologist.

Cogan, D. G., Kinsey, V. E., and Drinker, P. Infrared therapy of flash keratoconjunctivitis. *Jour. Amer. Med. Assoc.*, 1943, v. 123, Dec. 4, p. 883.

Infrared therapy was of no benefit in keratoconjunctivitis produced in rabbits by exposure to a mercury-vapor arc.

George H. Stine.

Culler, A. M. War injuries of the eye. *United States Naval Med. Bull.*, 1943, v. 41, Nov., pp. 1557-1564.

The author reviews 118 cases treated in a Naval Base Hospital in the South Pacific. He emphasizes the similarity of the problems that confront the ophthalmologist in civilian and military practice. Although errors of refraction and ocular diseases such as iritis and corneal ulcer seem relatively minor conditions, they are responsible for incapacitation in 9/10 of the cases here reported. The most frequent war injuries are shrapnel wounds, which are usually binocular and multiple. Careful removal of the foreign bodies, sulfa drugs by mouth, atropine, 5-percent sulfathiazole ointment, and continued cold applications constitute the treatment recommended. The ocular injuries resulting from air raids include burns, blast injuries, and direct trauma. Burns are especially frequent in this war, because of the use of incendiary bombs. Immobilization of the lids by sutures and early skin grafts are recommended. Damage to the eyeball is frequent in all head injuries, especially those involving the cranial cavity. Choroidal tears and their frequent sequel, proliferative traumatic chorioretinitis, especially involving the papillomacular region, are often encountered. Mental stress and shock form an important ophthalmic element in battle casualties. Charles A. Bahn.

Kemal, Tarkan. A case of encapsulation of a foreign body beneath the bulbar conjunctiva. *Göz Klinigi*, 1943, v. 1, Aug., p. 10.

The right eye was injured by a small fragment of a bullet 25 years ago. Inflammation lasted three months. When the eye could be opened again, the foreign body was visible beneath the conjunctiva near the caruncle. The foreign body remains in the same position. It had done no damage to the eye.

J. Igersheimer.

Knapp, Arnold. Retinal detachment and trauma. *Arch. of Ophth.*, 1943, v. 30, Dec., pp. 770-774; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41.

Lyle, D. J. Eye manifestations of head injuries. *Jour. Amer. Med. Assoc.*, 1943, v. 123, Dec. 4, p. 873.

The author divides the traumas due to head injury into the main divisions of cerebral concussion, contusion, compression and laceration, hemorrhage, and skull fractures. The ophthalmologic manifestations are either sensory or motor disturbances. There may be oculomotor palsies, intraocular or extraocular, with fundus changes in a certain percentage of cases. The importance of the pupillary changes during the early and late stages, especially noted among the compressions, hemorrhages, and skull fractures, is stressed. The important pupillary reflexes which are variable during the course of the condition should not be masked by a cycloplegic, a weak, fleeting mydriatic being the choice for fundus examination. Fundus changes include arteriolar spasms with ischemia, venous congestion, edema of the disc, and choking in the more severe cases. Visual-field changes may remain as the result of irreparable damage to the visual system. (4 cases, 12 figures, discussion.) George H. Stine.

Malabehar Peña, Carlos. Does fluorescent light cause injury to the eyes? *Bol. del Hosp. Oft. de Ntra. Sra. de la Luz*, 1942, v. 2, Jan.-April, pp. 21-23.

On the basis of figures furnished by the manufacturers, the author emphasizes the relative absence of heat rays in the light of the fluorescent lamp and the quantitative approximation of ultraviolet rays to those of daylight. He concludes that this type of lighting is

not prejudicial or dangerous for the human eye.

W. H. Crisp.

Rocco, Alfredo. Intraocular foreign body. *Arquivos Brasileiros de Oft.*, 1943, v. 6, Aug., pp. 127-131.

The patient's left eye was struck by a foreign body which seemed to originate in whirling movements imparted to a tape measure in the hands of a passer-by. A wound found in the region of the upper limbus was closed with two sutures. The vision was soon completely abolished. When the patient came for examination by the author the eye, which was completely blind, showed conjunctival chemosis, and a steady discharge from the wound. On account of the evident panophthalmitis, the eyeball was enucleated. Section of the enucleated globe showed in the vitreous a very large metallic object corresponding in shape to the protective cap commonly attached to the extremity of a tape measure. The foreign body measured 2 cm. in its long diameter. The author emphasizes the desirability of an X-ray examination in any such case. (References, 1 illustration.) W. H. Crisp.

Stewart, D. D. S., and Lloyd, J. P. F. Transient slitlamp appearances due to concussion by small particles. *Brit. Jour. Ophth.*, 1943, v. 27, Nov., pp. 483-485.

The slitlamp showed the appearance of small gray plaques in the form of wreaths about 2 mm. in diameter, at the level of Descemet's membrane and the endothelium, in an eye injured by "back-fire" from the breech of a rifle. The wreaths did not intersect and were not contangential in any instance. The plaques were visible 30 hours after injury but had disappeared 15 hours later.

Superficial foreign bodies were removed and the eye was entirely quiet a week after the injury, the visual acuity being 6/6 with correction. It is suggested that the gray flecks which constituted the wreaths were optical effects from local variation in the index of refraction. (2 illustrations.)

Edna M. Reynolds.

Stieren, Edward. Intraocular foreign bodies. *Jour. Amer. Med. Assoc.*, 1943, v. 123, Dec. 4, p. 880.

The author stresses the importance of a careful history, the immediate use of tetanus antitoxin, and location of the foreign body by ophthalmoscope and X ray. He advises immediate enucleation of an eye if the wound of entrance involves the ciliary body. He has discarded the use of the giant magnet in favor of the hand magnet, and deplors the use of the magnet as a diagnostic instrument. The posterior route is preferred wherever possible; detachment of the retina is not to be feared if the scleral incision is cauterized by the application of phenol or diathermic micropunctures. Some retained nonmagnetic foreign bodies, such as glass, may be well tolerated for years. Nonmagnetic metallic foreign bodies are dangerous and difficult to remove, phthisis bulbi resulting from loss of more than one fourth of the vitreous bulk or from extensive disturbance by instrumental manipulation. (Discussion.)

George H. Stine.

Tibbles, Sidney. Burn of cornea from molten wax. *Brit. Med. Jour.*, 1943, Oct., p. 547.

A patient complained of loss of sight after some wax flew between the eyelids while flicking out a lighted wax taper. The cornea appeared normal, but on examination through the loupe a

perfectly transparent layer of wax was seen covering two-thirds of the cornea as if a contact glass was lying on it. The cornea did not stain with fluorescein until after the wax was removed, whereupon most of the vision was restored. The erosion was superficial, only the epithelium being affected. It is reasonable to assume that a fine layer of vapor protected the cornea.

SYSTEMIC DISEASES AND PARASITES

Carrasco y de Mier, M. **Ocular disturbances of dental origin.** Jour. Internat. College of Surg., 1943, v. 6, July-Aug., p. 322.

Carrasco y de Mier advises correction of all dental disease before operations involving the opening of the globe. Ocular infections may take place (1) by direct continuity, (2) indirectly through sinus disease, (3) by the vascular route, especially venous channels, or (4) as the effect of substances producing allergy. To date there is no proof of the transmission of infection through the lymphatics, but reflex nervous affections are common, and may result in ocular vasomotor and secretory changes. Eugene M. Blake.

Parsons, J. H. **Eye diseases in elderly patients.** The Practitioner, 1943, v. 150, June, p. 329.

This paper presents a brief survey of ocular conditions encountered in senile patients, including refractive changes, arcus senilis, miosis, incipient cataract (with controlled use of mydriatics for central opacities), and glaucoma. Of the vascular disturbances the author mentions thrombosis of the central vessels, and arteriosclerotic retinal changes.

Benjamin Milder.

Spies, T. D. **The natural occurrence of riboflavin deficiency in the eyes of dogs.** Science, 1943, Oct. 22, p. 367.

In families showing deficiency diseases the household pets were often found to be emaciated and weak. Subsisting on table scraps mainly, such animals were suspected of having nutritional deficiencies. It was not uncommon to find black tongue in dogs. Recently eye symptoms similar to the ocular lesions of riboflavin deficiency in human beings were observed in dogs.

Four dogs from the homes of families suffering from deficiency were studied. Most marked was photophobia. Pronounced injection of the scleral and palpebral conjunctiva was present. The vessels were tortuous and unusually dilated. Slight rotary nystagmus was present. Along with these symptoms were those of pronounced black tongue. Slitlamp examination could not be made. Treatment with nicotinic acid and riboflavin promptly and completely relieved these animals. This suggested the presence of a mixed deficiency disease. Francis M. Crage.

Woods, A. C. **The influence of sensitivity and immunity on ocular tuberculosis.** Pennsylvania Med. Jour., 1943, v. 46, Aug., p. 1133.

The material of this article was covered in detail in the series published in the Archives of Ophthalmology from 1938 to 1942.

Desensitization of rabbits with tuberculo-protein markedly shortens and diminishes the severity of ocular tuberculosis. Thirty percent of a group of immune-allergic rabbits desensitized by frequent doses of tuberculin failed to develop ocular tuberculosis following the introduction of living tubercle bacilli. Five percent of the group in

which desensitization was stopped at the time of ocular inoculation failed to develop tuberculosis. Two percent of a control group of immune-allergic rabbits not desensitized failed to develop ocular tuberculosis. Incubation times for the reacting rabbits were 7, 4, and 2 weeks respectively.

Since, clinically, secondary ocular tuberculosis is frequently present in immune allergic states, the effect of a desensitization procedure after the establishment of a definite ocular tuberculosis was examined. Desensitization of rabbits which had a healed systemic tuberculosis was begun 17 days after inoculation of the eyes with tubercle bacilli. A marked focal reaction occurred in all the animals at the start of tuberculin therapy. The activity of the ocular process however gradually dropped in this group till at the end of the 22nd week only one was active in the treated group, while 12 were active in the control group (43 eyes each). At the end of five weeks only four of the treated group showed ocular tuberculosis, while 25 of the control group were active.

In rabbits, repeated intracutaneous

injection of tuberculin controls ocular sensitivity and exerts a favorable effect on tuberculous infection already present or subsequently produced.

HYGIENE; SOCIOLOGY, EDUCATION, AND HISTORY

Case, P. H. Recent advances in ophthalmology of interest to the general practitioner. *Southwestern Med.*, 1943, Sept., p. 213.

In discussing ocular chemotherapy the sulfonamides receive the entire attention of the author. The surgical advances include corneal sutures and intracapsular extraction. Sodium-pentothal general anesthesia has helped in the highly nervous and in so-called "bad actors."

Advances in the treatment of squint, aniseikonia, avitaminosis, and color blindness are discussed. Orthoptics seems to be of proved value and is being more generally accepted. Preventive measures are being increasingly employed in industrial ophthalmology.

Francis M. Cragé.

Dr. Carl Koller, New York, New York, died March 21, 1944, aged 86 years.

SOCIETIES

The Reading Eye, Ear, Nose, and Throat

Society, Reading, Pennsylvania, held a joint meeting with the Philadelphia Laryngological Society, January 19, 1944, in Philadelphia. Included in the program was a paper by Dr. James E. Landis of Reading on "Why we should organize a Pennsylvania Academy of Ophthalmology and Otolaryngology."

The Brooklyn Ophthalmological Society held its regular meeting February 17, 1944. The guest speaker was Dr. Donald J. Lyle of Cincinnati who presented a paper on "Diagnosis of visual losses with normal fundi." The discussers included Dr. Abraham M. Rabiner, Dr. E. Jefferson Browder, and Dr. Ralph I. Lloyd.

At the meeting of the Cleveland Ophthalmological Club on February 15th, Dr. William Thornwall Davis spoke on the "Diagnosis and treatment of accommodative squint."

The Washington, D.C., Ophthalmological Society held its meeting on March 6th at the District of Columbia Medical Society Building. The guest speaker was Dr. Ramón Castroviejo of New York City who discussed "Keratetectomies and conjunctival plastics." A report on "A case of Coats's disease" was made by Dr. H. C. McKnew. Also included in the program were the following case presentations: "Circinate retinitis" by Dr. Bernard J. Gurwin; "Laceration of the globe" by Dr. Thomas R. Rees; "A case of plastic prosthesis" by Dr. Ernest Sheppard; and "Neurofibroma of the eyelid" by Dr. Inez E. Wilber.

On January 26, 1944, the Reading Eye, Ear, Nose, and Throat Society had as its guest speaker, Dr. Henry S. Ruth of Merion, Pennsylvania, president of the American Board of Anesthesiology, who spoke on the developments of the various Specialty Boards as well as the future in anesthesiology. This meeting was attended by all diplomates of Specialty Boards residing in Berks County.

Among the speakers at the symposium sponsored by the industrial health committee of the Utah State Medical Association on January 19th was Major John E. L. Keyes (MC), A.U.S. The subject of his paper was "Ophthalmology in industry."

Dr. William Thornwall Davis gave a paper on "Differential diagnosis of paresis of the right superior oblique or left superior rectus"

before the New York Academy of Medicine on February 21, 1944, in New York City.

The annual postgraduate industrial, medical, and surgical conference of the Michigan State Medical Society will be held on April 6th at the *Horace A. Rackham Educational Memorial* in Detroit. Dr. Melvin H. Pike of Midland will speak on "Eye pathology due to exposure to organic solvents."

There will be a meeting of the Association for Research in Ophthalmology, Inc., in June of this year. The meeting will be held at the Sherman Hotel in Chicago just prior to the meeting of the American Medical Association; namely, on June 13, 1944.

Any member wishing to present a paper or contribute to the program is requested to com-

municate with Major Brittain F. Payne, The School of Aviation Medicine, Randolph Field, Texas.

An interesting meeting with a varied program is anticipated, and all members who are able to attend are urged to do so.

PERSONALS

Among those on whom a full professorship was conferred by the Emory University School of Medicine, Atlanta, Georgia, was Dr. Grady E. Clay, professor of ophthalmology.

Copies of Bielschowsky's "Lectures on motor anomalies," second edition, can be obtained from the Dartmouth College Publications, at Hanover, New Hampshire, price \$1.50, postpaid.

LEIOMYOMA OF THE IRIS*

A CASE REPORT

WILLIAM THORNWALL DAVIS, M.D., ERNEST SHEPPARD, M.D.,
AND WALTER J. ROMEJKO, M.D.
Washington, D.C.

Duke-Elder¹ referring to myomata states, "In the iris, they usually form sharply circumscribed tumors, appearing as yellowish-gray nodules without clinical symptoms, which grow slowly and are relatively benign, but if not completely excised, may recur (Verhoeff, 1936). Clinically, a myoma is quite indistinguishable from a malignant melanoma and for this reason the eye has usually been enucleated.

"While a myoma is impossible to diagnose clinically, its pathological recognition is by no means easy. The neoplasm is characterized by closely packed bundles of long, spindle-shaped cells with an eosinophilic cytoplasm and rod-shaped nuclei arranged in palisade-like rows (Fig. 2040): these are bound together with myoglia fibrils coursing along the cells and coalescing to form large fibers at their terminal processes (Fig. 2041). The picture resembles a spindle-celled malignant melanoma, the difference being that the cells of the latter are rarely distinctly spindle-shaped but terminate in and send off laterally, ill-defined processes anastomosing with those of neighboring cells to form a syncytium.

"It is only possible to distinguish be-

tween the two by differential staining (Mallory's phosphotungstic haematoxylin) and by the demonstration of the myoglia fibers by gold impregnation; and since these methods are comparatively recent, the cases reported by the older writers must be viewed with suspicion. The only three to be unquestionably demonstrated are those of Verhoeff (1923), Frost (1937), and Ellett (1939) (Fig. 2042). They seem to be associated with the sphincter muscle."

In Verhoeff's² case, the tumor was removed, apparently completely, on May 21, 1904. When the eye was dressed the next day it was found that a large portion of the tumor remained, giving the impression that none had been removed. Further attempts at removal with forceps and suction were unsuccessful. The eye was not enucleated until May 19, 1920, 16 years after the original operation. This was the first case in which the tumor was demonstrated by special staining. Of interest is its slight malignancy in that there was no material increase for 16 years. It arose from the surface of the iris by a constricted base and remained alive in spite of the fact that it was completely severed from the iris; its new blood vessels were derived from the wound. The original tumor did not invade the iris stroma nor involve the filtration angle. Histologically it showed no mitosis.

Frost's³ case is the second "In which

* From the Department of Ophthalmology, George Washington University Medical School. Read in part before the Washington, District of Columbia, Ophthalmological Society, February 15, 1943.

the pathologic findings are sufficiently definite to justify this diagnosis." The eye had been examined periodically for six years, prior to the tumor's appearance in August, 1934, and was enucleated in March, 1935, because several consultants thought the tumor was a sarcoma.

Ellett's⁴ case had had an irregular pupil for 5 years prior to the appearance of the tumor, which was of 15 years' duration. This eye also was enucleated because the tumor clinically resembled sarcoma.

Van Heuven⁵ has reported a case of leiomyoblastoma of the iris, and Was-senaar⁶ has reported a case of leiomyoma of the upper lid.

Collins and Mayou⁷ state, "The points relied on in diagnosing these growths as myomata rather than spindle-celled sarcomata have been: the position in which they started, their slow rate of increase, the similarity in the shape and size of their cells to unstriated muscle fibers and the rod shaped appearance of their nuclei."

Reëxamination of Zentmayer's⁹ case proved it to be a leiomyoma.

CASE REPORT

M. L., a woman, aged 27 years, was first examined on November 16, 1942, when she complained of a brown spot in the iris of the right eye which had been present as long as she could remember. She had injured the eye with a wire when a child, but of this there was no evidence. The history suggested a superficial scleral injury. The family history was irrelevant.

The ocular examination was essentially normal except for the tumor in the inferior temporal quadrant of the right iris, as shown in figure 1a. The physical examination by Dr. Lewis Ecker was normal. There was no evidence of primary tumor elsewhere. The blood Wassermann and Kahn tests were negative. There was 4 percent of eosinophiles, otherwise the hemogram was normal.

The tumor and adjacent iris tissue was removed on January 5, 1943 (fig. 1b). The postoperative course was uneventful. Pathologic reports were made by Col. J. E. Ash, Army Medical Museum, accession 87990, as follows:

"Gross: the specimen consists of a pale fibrous mass measuring 9 by 6 by 3 mm. There is an opaque elevated nodule 3 mm. in diameter on the anterior surface and brown pigment on the posterior surface.

"Microscopic: The tumor is composed of interlacing fascicles of non-pigmented, spindle-shaped cells with long fibrillar processes of smooth muscle character and oval, sometimes nucleolated nuclei. There is no evidence of intercellular collagen. The bundles of tumor cells are divided by an interlobular, richly vascular connective tissue stroma. The vessels are generally thin-walled but not of the sarcoma type. The tumor probably arises from iris muscle. Diagnosis: Leiomyoma; iris" (fig. 2).

SUMMARY

1. Leiomyoma of the eye and its adnexa is rare. Cases have been reported involving the iris, ciliary body, and upper lid.

2. Of clinical importance is its slow growth and long duration, the absence of symptoms, the lack of any tendency to invade the surrounding structures or the filtration angle. With these characteristics it would seem advisable to consider excision before enucleation.

3. It is clinically impossible to differentiate leiomyoma from malignant tumors of the iris.

We wish to express our appreciation to Heleanor Campbell Wilder for kind cooperation in expediting the examination of the specimen and to Mr. Roy Reeves of the Army Medical Museum for preparation of the microscopic illustration.

SUPPRESSION AMBLYOPIA*

H. SAUL SUGAR, MAJOR (M.C.), A.U.S.

Vancouver, Washington

Although considerable attention has been paid to the subject of amblyopia, uncertainty remains with regard to its status. Views on its relation to squint have traversed the length of the pendulum's arc, as shown by Peter's¹ statement that "amblyopia in the squinting eye was formerly regarded as one of the causes of monocular squint but the lowered vision which is found is now interpreted as a symptom of squint and not as its cause." Conclusions drawn from a careful observation of amblyopia in patients with and without squint do not agree with either extreme. For this reason a statistical study was made of 200 consecutive amblyopic patients at the Barnes General Hospital.

The term "amblyopia" refers to a functional disorder characterized by a reduction of visual acuity which is not correctible to normal by optical means. Fuchs² has classified the conditions denoted by the term as follows: 1. Disturbances of sight seated in the eye itself—(a) congenital amblyopia, (b) ambly-

opia ex anopsia. 2. Disturbances of sight of central origin.

This classification has been used for many years but has several obvious flaws. First, there is considerable clinical evidence that so-called amblyopia ex anopsia is not seated within the eye itself but is of cerebral origin. The process of visual interpretation or "seeing" takes place in the brain, so any inhibition of the retinal image must be cerebral. Second, the term congenital amblyopia has been used to designate a condition which, according to Fuchs, "we assume to exist in those cases in which weak sight has existed for a long time, and in which all other causes for it can be excluded." In most of these cases the amblyopia would better be considered idiopathic. Third, Fuchs used the term amblyopia ex anopsia for amblyopia from nonuse resulting from such obstacles to vision as opacities in the cornea, lens, or pupil (pupillary membrane), or from disuse occurring in eyes affected with high refractive errors or squint since childhood. The amblyopia resulting from congenital opacities in the ocular media is not the same as that occurring in eyes

* From the Eye Clinic, Barnes General Hospital.

without pathology since it has been shown that the macula may not develop normally without the stimulus of the retinal image. In these cases the vision usually remains poor no matter how early the cataract is removed even after bilateral operations. If this type of amblyopia were acquired it would be expected that the vision would improve in one eye of patients operated on for bilateral congenital cataracts. In individuals with cataract acquired later in life the visual acuity usually is correctible to normal upon removal of the cataract even if the visual obstacle has been present for many years. The amblyopia due to congenital visual obstacles would more properly be termed *congenital amblyopia*.

A fourth possible objection to Fuchs's classification is the use of the term *ex anopsia*, meaning "due to not seeing" or "due to disuse." The question of its justification will be considered after a presentation of the results found in my series of amblyopic patients.

Abraham³ has presented the following classification which is based on his view that the term *ex anopsia* is a misnomer and that suppression is the important factor. A. Congenital amblyopia. B. Acquired amblyopia: 1. Passive suppression (ametropic)—(a) bilateral; (b) unilateral. 2. Active suppression—(a) bilateral; (b) unilateral (squint).

Although I agree entirely with the use of the term suppression rather than *ex anopsia* there are certain objections to this classification. First, the same comment referred to in criticizing Fuchs's classification applies to the use of the term congenital amblyopia when idiopathic amblyopia is meant. Second, I do not believe bilateral-suppression amblyopia exists except in patients with hysterical amblyopia. The term suppression refers to a psychologic inhibition of the retinal image. When suppression becomes habitual, amblyopia is the result. Patients may have

alternating suppression, as in patients with alternating strabismus, but amblyopia occurs only in one eye. Occasionally one sees a person with a high hyperopia which cannot be corrected beyond 20/40 in each eye; but this is a matter of lack of discrimination rather than suppression. It is frequent in young children to find a lower visual acuity than is commensurate with the refractive error. These same children later have normal visual acuity. At any rate, I do not believe subgrouping as to involvement of one or both eyes is justified. Third, Abraham considered passive suppressive amblyopia as due to lack of correction, or late correction of refractive error, and active suppression amblyopia as due to uncomfortable or confused binocular fixation. Whether such a subdivision is justifiable is another of the questions for which an answer is sought in the present study.

A classification which I believe more adequately divides the various types of amblyopia is simply:

- (1) Suppression amblyopia (so-called amblyopia *ex anopsia*)
- (2) Idiopathic amblyopia
- (3) Congenital amblyopia (due to congenital visual obstacles)
- (4) Discrimination amblyopia (bilateral)
- (5) Hysterical amblyopia
- (6) Amblyopia of toxic and neurologic disease

Only the first two groups concern us here.

RESULTS

Of a total of 200 consecutive amblyopic patients 124 had no deviation even under cover, 63 were or had been convergent squinters, 8 were divergent squinters, and 5 had very fine corneal opacities which were in themselves not sufficient to account for the reduced visual acuity. Each group was subdivided into the following

categories, according to the refractive error found under homatropine cycloplegia:

- (1) Anisometropia of at least 1.50 diopters of sphere, 1.50 diopters of cylinder, or both;
- (2) High isohyperopia or isoastigmatism;
- (3) Low refractive error or emmetropia.

The value chosen as the criterion of anisometropia was entirely arbitrary. It appeared more reasonable than the 0.5 diopters used by Worth and Lagleyze.⁴ This, of course, makes a great deal of difference in the final statistical breakdown. Clinically an anisometropia of 0.75D. often causes discomfort, but suppression apparently does not occur unless the difference is 1.50 to 2.00 diopters.

I. AMBLYOPIA WITHOUT SQUINT

The group of 124 nonsquinting amblyopic patients was divisible according to the following refractive conditions:

- (1) Anisometropia 94 (75.8 percent)
- (2) High isohyperopia or isoastigmatism 18 (14.5 percent)
- (3) Low refractive error or emmetropia 12 (9.7 percent)

The anisometropia averaged 3.40 diopters of spherical difference in 69 cases and 4.02 diopters of anisoastigmatism in 25 cases. In those cases where both spherical and astigmatic anisometropia was present, only the higher of the two was considered. The remaining 30 patients had a difference in correction of less than 1.50 diopters of sphere, cylinder, or both. Of these 17 with high isohyperopia averaged 5.05 diopters of hyperopia in the amblyopic eye and 4.49 diopters in the nonamblyopic eye. The astigmatic correction in one case of isoastigmatism was 2.75 diopters each eye. The 12 patients with low refractive error averaged 0.99 diopter of spherical error in the

amblyopic eye and 0.65 diopter in the nonamblyopic eye. One of these patients had had the amblyopic eye patched for eight weeks during childhood because of lid disease. In this group suppression of the intermediate as well as of the central field of the squinting eye was present in those with less than 20/50 visual acuity (corrected) in the amblyopic eye. The tests were made with a stereoscope and Guibor cards.

II. AMBLYOPIA WITH CONVERGENT SQUINT

This group of 63 patients was affected only by comitant squints, some of which may have been precipitated by ocular pareses. They were separable into the following categories:

- (1) Anisometropia 18 (28.6 percent)
- (2) High isohyperopia or isoastigmatism 29 (46.0 percent)
- (3) Low refractive error or emmetropia 16 (25.4 percent)

The anisometropia averaged 2.94 diopters of spherical difference in 16 cases and 4.12 diopters of anisoastigmatism in 2

cases. The remaining 45 patients had a difference in correction of less than 1.50 diopters of sphere, cylinder, or both. Of these, 28 had high isohyperopia averaging 3.83 diopters in the amblyopic eye and 3.67 diopters in the nonamblyopic eye. A single case of high isoastigmatism required a correction of 2.75 diopters of

The anisometropia averaged 3.81 diopters of spherical correction in four cases and 3.37 diopters of astigmatic correction in two cases. The two patients with low refractive error averaged 0.87 diopter of spherical correction for the amblyopic eye, and 0.50 diopter in the nonamblyopic eye.

TABLE 3
REFRACTIVE CORRECTION IN 8 CASES OF
AMBLYOPIA WITH DIVERGENT SQUINT

No.	Age	Amblyopic Eye		Nonamblyopic Eye (Corrected Vision 20/20 Each) Correction (Cycloplegic)

8	26	20/400	+1.50	+0.75

cylinder in the amblyopic eye and 2.25 diopters in the nonamblyopic eye. The remaining 16 patients with low refractive error or emmetropia required an average of 0.96 diopter of spherical correction for the amblyopic eye and 0.60 diopter for the nonamblyopic eye.

III. AMBLYOPIA WITH DIVERGENT SQUINT

This group consisted of only eight pa-

IV. AMBLYOPIA WITH FINE CORNEAL OPACITIES

This group consisted of five patients, four nonsquinting and one with divergent squint. All were believed to have had good visual acuity in both eyes before the occurrence of corneal ulcer. They are separable as follows: (1) Anisometropia 4 (80 percent); (2) Low refractive error 1 (20 percent).

The anisometropia averaged 2.70 diopters of astigmatic difference in three cases and 2.50 diopters of spherical difference in one case. The single patient with low refractive error required 1.75 diopters of spherical hyperopic correction in the amblyopic eye and 1.00 diopter in the nonamblyopic eye.

The results may be summarized as follows:

	Anisometropia	High Isohyperopia or Isoastigmatism	Low Refractive Error
	no. percent	no. percent	no. percent
124 Nonsquinting amblyopia	94 (75.8)	18 (14.5)	12 (9.7)
63 Amblyopia with convergent squint	18 (28.6)	29 (46.0)	16 (25.4)
8 Amblyopia with divergent squint	6 (75)		2 (25)
5 Amblyopia with fine corneal opacities	4 (80)		1 (20)
Total	122 (61)	47 (23.5)	31 (15.5)

tients, separable into two groups: (1) Anisometropia 6 (75 percent); (2) Low refractive error 2 (25 percent).

COMMENT

Of the series of 200 amblyopic patients, the condition of those (15.5 percent)

without significant refractive error may be considered as idiopathic. The discussion to follow will concern only the remaining group of 169 with significant refractive error.

If one considers the two large groups of the nonsquinting amblyopic and the amblyopic with convergent squint it is apparent that the chief difference is the predominance of anisometropia among the nonsquinters and of isometric high hyperopia or astigmatism among the convergent squinters. The anisometropia was

more frequently spherical than astigmatic, in contrast to Abraham's findings.³

These findings suggest some causal relationships which must necessarily be largely theoretic. Our consideration depends in part on whether an eye must focus images sharply early in life to develop normally before the binocular reflexes develop. If this were true those infants whose eyes are highly astigmatic at birth would never be correctible to 20/20 with glasses later. If we assume that each visual element develops normally whether the image is sharp or blurred, then what Abraham calls passive suppression does not occur. With this assumption in mind let us consider anisometropia first. It must be agreed that aniseikonia exists in the uncorrected anisometropic. When the binocular reflexes begin to develop fusion is found to be difficult or uncomfortable. Psychologic inhibition of the disturbing macular image is resorted to. This process

is known as suppression. As time goes on the suppression becomes more diffuse. If one imagines the visual field as an island shown in cross-section, representing the horizontal meridian of the retina (Roenne and Traquair), suppression involves the vision in a manner such as to level off the macular peak and eventually to depress the entire field. The periphery of the temporal field is least affected since it is not overlapped by the field of the other eye. When suppression becomes habitual amblyopia results. Frequently suppression may be reduced by occlusion of the nonsuppressing eye. However, this is not permanent unless the factors causing the suppression are removed.

An interesting type of meridional suppression in astigmatic anisometropia was described by Martin.⁵ He found the visual acuity in the meridian of greatest diffusion to be one half or one third of that in the opposite meridian.

The process of suppression in anisometropia is often observable in patients following operation for monocular cataract. For a short while after operation the patient is conscious of the larger blurred image from the eye that has been operated on. In a relatively short time it is suppressed but may be called into consciousness if proper correction is placed before this eye. The same process is experienced by microscopists and watchmakers who learn to suppress the macular impression from one eye, at first voluntarily and later unconsciously.

In cases of high isohyperopia or high hyperopic isoastigmatism another process apparently goes on. In these patients there is a need for great accommodative effort in order to get clear vision. As the binocular reflexes develop accommodation and convergence become associated. The convergence resulting from the desire for clear binocular vision causes a

diplopia that is very confusing. To avoid this, suppression takes place in the more ametropic eye. With habitual suppression, amblyopia results. The fact that isometric high hyperopia is most frequent among the convergent squinters fits in well with the accommodation-convergence theory just stated. In these cases convergence continues to be associated with accommodation even though amblyopia exists. This explains why the deviation in many cases of monocular convergent squint with amblyopia is reduced when convex lenses are worn. In other cases, if the hyperopia exceeds the ability of the accommodation to permit clear vision, no squint develops (Chavasse).⁴ In my series of amblyopic patients the degree of hyperopia in those convergent squinters with isohyperopia was less (average of 3.83 diopters in the amblyopic eye and 3.67 diopters in the nonamblyopic eye) than in nonsquinters with isohyperopia (average of 5.05 diopters in the amblyopic eye and 4.49 diopters in the nonamblyopic eye).

In the cases of divergent squint, the majority were anisometropic. Suppression unquestionably preceded the amblyopia in these cases.

In the cases with fine corneal opacity the original ulcer had been present during early childhood. The suppression could have been produced either by the obstacle to vision at the early age or by the resulting change in refraction due to scarring, which usually produces anisometropia, particularly the astigmatic type.

During the period of binocular-reflex development, fusion may develop to various stages both in the anisometropic and in the high isohyperopic, but any sudden weakening factor such as shock or an acute infectious process may cause the attained level of fusion to be too difficult to sustain, so that recourse will be had to

suppression. This accounts for the abrupt onset of many cases of strabismus.

In many instances of comitant squint, suppression precedes the deviation, whereas in others (probably including those with abrupt onset associated with illness or shock) suppression follows diplopia; so suppression cannot always be considered a result of the squint. In any patient with a paretic extraocular muscle the resulting diplopia leads to secondary suppression. Many cases of comitant squint are probably of paretic origin. Thus suppression and amblyopia may *precede or follow* the development of squint. This type of amblyopia *always follows suppression* and should be designated properly as *suppression amblyopia* and not as "ex anopsia." The process is always an active one rather than simply a passive loss of acuity from neglect, which the term "ex anopsia" implies. For the same reason Abraham's subdivisions into active and passive types do not appear to be justifiable.

Further evidence that the development of amblyopia is an active process is shown by the presence of a central scotoma which may be either relative or absolute. Uththoff⁶ found a scotoma in 55 percent of his cases whereas Heine observed it in 90 percent. Uththoff was convinced that central scotoma is constant in marked amblyopia. Evans, Peter, and Travers have done extensive work in this field. Best⁷ demonstrated that during microscopy an absolute central scotoma was present, without any involvement of the peripheral field. The improvement by occlusion and the transfer of the amblyopia from the poor eye to the better one by occlusion are additional convincing observations. The transfer of amblyopia apparently is possible only during the first few years of life.⁸ That the age factor is important is shown also by the fact that

amblyopia rarely occurs in squinting children if the squint develops after the age of seven. It explains the relative infrequency of amblyopia in cases of divergent squint, most of which develop later.

It is obvious that amblyopia may or may not be associated with squint. Most nonparetic squints probably result from *suppression* plus an *additional factor*, either the accommodative stimulus to convergence, or simply the assumption of the dissociated position by the suppressed eye. Idiopathic amblyopia must be considered as due to suppression resulting from such factors as patching one eye in infancy or childhood and possibly hemorrhages due to birth traumata.

CONCLUSION

1. In disagreement with Peter's statement that amblyopia in squinting eyes is a symptom of squint and not its cause, suggestive evidence has been presented indicating that suppression and amblyopia precede the development of certain nonparetic squints and follows the de-

velopment of other nonparetic squints and those of parietic origin.

2. Anisometropia is the predominating associated factor in nonsquinting amblyopic subjects, whereas high isohyperopia is the most frequent factor in cases of amblyopia with convergent squint.

3. Nonparetic squint probably requires suppression plus another factor for its development. This may be the accommodation-convergence relationship or simply the assumption of the dissociated position after suppression has been obtained in one eye. The age factor is obviously of considerable additional importance.

4. Suppression amblyopia is a more accurate term than amblyopia ex anopsia, implying, as it does, an active rather than a passive process.

5. The conclusions drawn may be of aid in adding links to the chain of evidence as to the cause of squint. Further clarification of the reason for normal muscle balance in a large number of amblyopic subjects, particularly a possible relationship to peripheral fusion, is necessary.

EXTRADURAL DIPLOIC EPIDERMIDS PRODUCING UNILATERAL EXOPHTHALMOS*

EDWIN HALE THORNHILL, M.D., AND BANKS ANDERSON, M.D.
Durham, North Carolina

Unilateral exophthalmos presents one of the most challenging diagnostic problems in ophthalmology. Among the unusual causes of this condition are the extradural diploic epidermoids. Such tumors are not to be confused with the so-called oil cysts or cholesteatoma of the orbit.¹ While both arise embryologically as a result of identical developmental defects, the point of origin of the diploic epidermoid results in characteristic bony changes which should aid greatly in the diagnosis of this condition.

In the neurosurgical literature the occasional reports describing these tumors have been collected by Bailey,² King,³ and, most recently, by Rand and Reeves.⁴ Since no such adequate description of this unusual condition can be found in the ophthalmologic literature; since, as a matter of fact, considerable confusion exists as to the actual nomenclature applied to the tumors under consideration, a summary of these papers would seem to add greatly to the worth of this report. The tumors in question have been described under the heading of "Pearly tumors," "Cholesteatoma vera," and "Epidermoids." This confusion is the result of the perpetuation of terms which entered the literature when the etiology and nature of the lesions were poorly understood. The situation is greatly clarified by sketching in historical perspective the development of our knowledge of the condition, and by bringing into focus controversial ideas as to etiology contemporary with the various stages in this development. In this sketch

we have drawn freely from the aforementioned papers.

These tumors are epithelial in origin. They are thought to originate from epithelial-cell rests which become pinched off from the epithelial body covering during development. Such rests, remaining quiescent in early life, for some reason become activated at maturity. These primary epidermoids should not be confused with secondary epidermoids such as might result from the migration of epithelial cells through a marginally perforated ear drum, as is the result of blockage of a sinus after migration of such cells, or even as the result of the traumatic implantation of such cells within the diploic spaces. Macroscopically and microscopically there is no distinction between the two. The location of the growth in an area in which there could be no possible contact with mature epithelium is the distinguishing feature. The epidermoid differs from the dermoid in that its wall contains only squamous or basal epithelium. Such a tumor, lacking the sweat and sebaceous glands of the true dermoid, is potentially unable to develop into the so-called oil cyst of the orbit. It should present in all or in part the following characteristics: Theoretically the wall of the tumor should be composed of three layers. There should be an outer, relatively acellular, connective-tissue layer supporting a thinner, second, epithelial layer. The connective-tissue layer should consist of scattered fusiform and stellate fibroblasts embedded in a mass of intercellular fibers with few blood vessels. The second layer internal to that just described should consist of stratified squamous epi-

*From the Ophthalmological Division, Surgical Department, Duke Hospital and Medical School.

thelium, the cell layers varying in thickness. The cells in the outer layers should be flattened, parallel to the surfaces, and should have no nuclei. Those composing the inner layers should be more cuboidal in shape and perpendicular in direction. Keratohyaline granules should be present in the cytoplasm of these cells, and for the most part the nuclei should be well preserved. Intracellular bridges may be seen. The inner third layer should consist of cornified epithelium. From this layer inward the epithelial debris accumulates as the cells are cast off. The lining membrane may be calcified so that the tumor is surrounded by an eggshell-like wall.

The first report of a tumor of such characteristics is credited to Cruveilhier (1829). In this report the growth was described as a "Tumeur perlée." By means of this term an attempt was made to describe the nodular and highly refractile surface of the tumor. In his report, Cruveilhier noted that two similar tumors had been seen by LePrestre and Dumeril, in 1807. In 1938, Johannes Mueller reported two tumors which fall within this group. Mueller was most impressed by the cholesterol crystals found in these cases and applied the name *cholesteatoma*. One of Mueller's two cases was the first reported case of what we now term *extradural diploic epidermoid*. Virchow, in 1855, reported four additional cases falling within this group. He objected to the term *cholesteatoma*, pointing out that cholesterol crystals were not a constant finding. In common with Cruveilhier, he elected the term "*Perlgeschwülste*" as being most descriptive. In the meanwhile, Von Remak, in 1854, first suggested that these tumors arose from embryonic epithelial-cell rests. These investigations, according to King, afforded the basis for the term *epidermoid* later used by Bostroem (1897). Cushing⁵ (1922) observed that these tumors, quite rare as a group,

occurred yet more infrequently when originating in the cranial diploe. The extreme rarity of the condition is further appreciated when it is realized that in Cushing's series of 2,500 verified intracranial tumors there were, according to Mahoney,⁶ only 15 epidermoids—an incidence of 0.6 percent. The same author was able to find in the entire literature only 142 true epidermoids—of these only 23 were of the diploic type. Cushing reported one such case and collected from the literature six others. To the group he applied the term *epidermoid cholesteatoma*. More recently, Rand and Reeves have stated that: "From recent publications it is becoming increasingly evident that the terms 'dermoid' and 'epidermoid' are more frequently used in describing these neoplasms."

Diagnosis. Cushing, in 1922, stated that insofar as he knew the condition had never been diagnosed except at autopsy or operation. He also stated, however, that "They are capable of recognition roentgenologically, owing to the sharp bony defect and are capable also of complete surgical removal if approached by a flank rather than by direct attack in order that the epidermal membrane may be completely removed." Since the appearance of Cushing's paper, King, Olivecrona, and perhaps others, have on the basis of X-ray findings ventured preoperative diagnosis. The roentgenologic characteristics of the cranial defect produced by this condition are said to be positive and unmistakable. The outstanding and differentiating feature is the sharply defined, dense, white, scalloped margin found in no other condition. Any other eroding lesion, regardless of its nature, produces a defect the margins of which are poorly defined, hazy, or perhaps even fuzzy and soft. King further states that in a typical defect produced by the diploic type in

which the inner table is more involved than the outer, when viewed so that the greatest diameter of the defect is shown, the latter has a scalloped dense clear-cut margin, showing that this margin is more compact than the remainder of the skull. One or more bony hiatuses may be observed in the skull. These represent areas in which the outer table has been completely destroyed. If the roentgenogram is taken so that one views the defect "on edge," as though looking at a saucer edge-wise, a dense line two or more millimeters wide is seen. This is due to the superimposition of the dense margins of the defect which brings the compact bony margins in alignment. The outer table may then be so thin as to be invisible in an underexposed film.

Other than the roentgenologic characteristics just described, there is nothing characteristic in the clinical findings. In 12 of the 14 cases of congenital epithelial tumor (dermoid or epidermoid) reported by Love and Kernohan⁷ headache was the presenting symptom. In general, headache, mental disturbance, convulsions, palpable masses or swellings, disturbances of gait, vertigo, and disturbances of vision have been the presenting symptoms. Exophthalmos has been noted in only a few cases. One should be alert to the possibility of such a lesion if a patient presents himself with a painless swelling associated with obvious bone erosion which has increased very gradually in size without other signs and symptoms.

In consideration of the rarity of the tumor, especially when so situated as to produce exophthalmus we feel justified in reporting the following case.

CASE REPORT

E. S., a 24-year-old white woman, a textile worker, was admitted to Duke Hospital for determination of the cause of a gradually increasing loss of vision in

the left eye of four years' duration. The past history was irrelevant insofar as any connection with the presenting signs and symptoms was concerned. At no time had there been evidence of inflammation in this area, nor any pain. There had been no suggestion of symptoms indicating increase in intracranial pressure.

Examination. The patient was a well-developed, obese, white woman, alert, coöperative, and in no distress. Except

Fig. 1 (Thornhill and Anderson). Exophthalmos due to cholesteatoma of the orbit.

for the exophthalmos of the left eye, there was a normal configuration of the head and face (fig. 1).

The right eye and adnexa were normal. The marked exophthalmos of the left eye was especially impressive—measured with the Hertel exophthalmometer this amounted to 5 mm. (O.D. 15 mm.; O.S. 20 mm.). The veins of the lid were not dilated. No pulsations were felt. There was no bruit; nor was there pain on pressure or movement, or any limitation of movement. A soft, nontender mass, rubberlike in consistence was palpable under the supraorbital ridge. The ridge had lost its smooth, rounded contour and was sharply defined. On downward gaze there was a definite momentary distortion of the sclera in the upper portion which would persist for an instant and then round out. The pupils were regular, equal, and reacted to light and accommodation. Ophthalmoscopic examination of the right eye was essen-

tially normal. The optic disc of the left eye appeared paler than normal with blurred edges, probably due to the high astigmatism. The vessels were not unduly full nor tortuous. There were tension lines in the retina in the supratemporal

Accessory clinical findings: Hemoglobin 90 percent, white blood cells 11,360 with a normal differential, Wassermann test negative, basal metabolism rate -4 , blood sugar 90 mg. per 100 c.c., serum cholesterol 208 mg. per 100 c.c.

Fig. 2 (Thornhill and Anderson). X-ray studies in a case of cholesteatoma of the orbit.

region, radiating laterally from a center adjacent to the papilla. The peripheral fields showed no constriction. The right eye was emmetropic. The left eye required a $-5.50D.$ cyl. ax. 180° for 20/20 acuity. No interesting nor pertinent information was obtained in the general physical examination of the body systems.

X-ray (fig. 2) report was as follows: "Films of the orbit and optic foramina showed no erosion around the foramina. The upper wall of the left orbit has been destroyed, and an area of excavation extends upward measuring more than 2 cm. in diameter. There is no new bone formation, and the process must be differentiated between Schüller-Christian's

disease and a cholesteatoma."

Impression: Retro-orbital tumor (unclassified).

Operation. Under gas-oxygen-ether anesthesia the left orbit was explored through a supraorbital incision. As the periosteum was elevated an oval defect of bone was uncovered just above the supraorbital ridge and at the junction of its outer and middle thirds. The defect was approximately 1.5 by 2 cm. in size.

In the more central portion the lamination became less conspicuous and finally indistinguishable from the central caseous core. These putty- and cheeselike contents were excavated with a spoon, after which the entire capsule was cleared away by meticulous piecemeal dissection. The inner table of the skull was found to have been completely eroded beneath this mass. The dura was intact but considerably depressed. The anterior superior

Fig. 3 (Thornhill and Anderson). The appearance of the mass exposed at operation. -

Through it protruded a nonpulsating yellowish-white avascular mass. As the periosteum was further deflected three smaller perforations contiguous to that first exposed were uncovered. These were 2, 2, and 3 mm. in diameter (fig. 3). The bone lying between these dehiscences was of tissue-paper thickness. By removing these three intervening bridges the four defects were converted into one large opening through which an oval mass approximately 3 cm. presented. The surrounding capsule was quite friable and, in the manipulation necessary for removal of the tumor it ruptured. The contents thus exposed consisted of an outer layer of shell, 1.5 mm. in width, of white puttylike material laminated in concentric layers parallel to the friable capsule.

wall of the orbit was also eroded and the contents depressed inferiorly. Careful search was made for any connection with any of the accessory nasal sinuses, but none could be demonstrated. The left frontal sinus was quite small and definitely medial to the area under discussion (fig. 2).

Immediately following the operation the eye receded to its normal position within the orbit.

The postoperative course was uneventful. Following operation the exophthalmometer readings were O.D. 15, O.S. 17. Vision was O.S. 20/300, with a $-5.00D.$ cyl. ax. 180° it equalled 20/20.

One month later the exophthalmometer readings were 15 O.U. Vision was O.D. 20/20, O.S. 20/20 with $+3.00 D.sph.$ \approx

-2.50D. cyl. ax. 180°. The fundus picture had not changed.

The *pathologic report* was as follows: "The pathologic specimen is material described as having been removed through the left orbit from the frontal region, and is said to have had the appearance at operation of a cholesteatoma. The material received includes approximately 14 gm. of tissue, which includes both irregular fragments of opaque, hyaline-like fibrous tissue and large irregular pieces of pinkish-gray, cheesy material. The irregular fragments break very easily on manipulation, compatible with the clinical description of the irregular hyaline strands which represent the capsular tissue; whereas the softer, grayish, cheesy material undoubtedly represents the evacuated contents. Grossly this tissue is compatible with the clinical diagnosis of cholesteatoma.

"The microscopic examination reveals for the most part two types of tissue. The first is represented by small irregular fragments of acellular, pale, eosin-staining, hyalinelike material. Nowhere in such fragments do we see anything which resembles connective-tissue cells nor anything which may be identified as epithelium. In some such fragments there is lamination with separation of adjacent keratinlike material. This tissue apparently corresponds to what was described at operation as the capsule. In addition there are also some fragments of tissue which may represent a part of this capsular tissue which has the appearance of elastic-tissue fibrils. There are also fragments of acellular, amorphous material in which no structure is evident. The lat-

ter tissue corresponds to the material so frequently seen within epithelium-lined cysts. However, nothing can be said in regard to its character inasmuch as material is not available for fat stains. There is no histologic evidence of cholesterol."

The microscopic picture of the tissue examined seems compatible with the clinical diagnosis of cholesteatoma. However, it must be pointed out that we are unable to identify the nature of the capsule and there is nothing to suggest either endothelium or epithelium.

SUMMARY AND CONCLUSIONS

Extradural diploic epidermoids producing unilateral exophthalmos are not usually considered among the possibilities in the differential diagnosis of the causes of this condition. None the less, the condition may exist in areas adjacent to the orbit and may be the cause of exophthalmos. The possibility that unilateral exophthalmos is due to such a lesion can probably be proved or eliminated by X-ray studies once the possibility is recognized by the typical scalloping of the edges with marginal increase in bone density demonstrated through proper angulation and exposure.

Complete removal and a cure was obtained in this case through the supra-orbital approach. It is doubtful whether this particular type of tumor ever occurs so far back in the orbit (the tumor arises from diploic spaces which are not present in the walls of the orbit) as to justify the transfrontal approach recommended by neurosurgeons.

CONGENITAL CATARACT AND OTHER ANOMALIES FOLLOWING GERMAN MEASLES IN THE MOTHER

ALGERNON B. REESE, M.D.*

New York

In Australia in the summer of 1940 there was a severe epidemic of German measles. Overcrowding due to the influx of military recruits might have contributed to the rapid spread of the disease and its virulent nature. In the first part of 1941 an unusual number of cases of congenital cataract appeared in Sydney. Dr. N. McAlister Gregg published, in the Transactions of the Ophthalmological Society of Australia, a report on "Congenital cataract following German measles in the mother" and subsequently a nationwide investigation was conducted by the National Health and Medical Research Council. The results of their findings are here reviewed and the author cites three similar cases seen in New York within the past few months.

GREGG'S FINDINGS

Gregg's report is based on 13 cases of his own, 7 of his colleagues' seen by him, with a total of 78 cases in all, including those reported by his colleagues to him for reviewing. The findings were as follows:

General. Most babies were small, ill-nourished, and difficult to feed.

Cataract. All of the babies had cataract from birth; all were bilateral cases except 16. The opacities were seen to fill the entire pupillary area when the pupil was un-

dilated; but after dilatation two main types were observed. In the first, the contrast was marked between the larger, dense, pearly-white central area and the smaller, clearer, more peripheral zone. In the second, the density of the cataract was more uniform throughout. The process involved all but the outermost layers of the lens and was considered to have begun quite early in the life of the embryo.

Vision. The response to light was sluggish, but the babies appeared to follow readily any movement of the light stimulus.

Nystagmus. In young patients this was absent, but in older babies, or in patients whose treatment had been delayed, it was present. Movements were of a coarse, jerky, purposeless nature, rather than a true nystagmus. It was a searching movement, indicating an absence of development of fixation. It was present after treatment was delayed beyond the age of three months.

Variations. Three patients had corneal haze denser in the center than in the periphery. After two weeks the cornea cleared and the typical cataracts were seen. In one of these cases, the mother developed cataract during the pregnancy at the age of 27 years.

Monocular cases. There were 16, of which 10 presented microphthalmia.

Heart. Of Gregg's 13 cases all but one

* From the Institute of Ophthalmology of the Presbyterian Hospital.

baby had a congenital heart condition. In the series of 78 cases, a congenital heart lesion was present in 44, while in many others the question was equivocal, evaded, or suspicious. Autopsy findings in three cases revealed a large patency of the ductus arteriosus, and the author understood that in autopsies performed elsewhere a similar condition was found.

Deaths. In the entire series 15 deaths were recorded. Several were from bronchopneumonia, and in three there was a sudden rise of temperature to 105° or even 106°F. followed by death within 24 hours.

Intolerance to atropine. In not a single instance has it been possible to continue the administration of atropine throughout treatment. Even after one or two instillations the patient exhibited considerable constitutional disturbance, with pyrexia, restlessness, irritability, and difficulty in feeding. In some cases the iris had an atrophic appearance. Full mydriasis could not usually be obtained.

Etiology. By a calculation from the date of the birth of the baby, it was estimated that the early period of pregnancy corresponded with the period of maximum intensity of the very widespread and severe epidemic in 1940 of the so-called German measles. Special attention, therefore, was paid to the history of the mothers during pregnancy, and in each new case it was noted that the mother had suffered from German measles early in her pregnancy and, most frequently, in the first or second month. In some cases, at the time of the disease she had not realized that she was pregnant.

Incidence of German measles in series. In all but 10 of the 78 cases a history of German measles during pregnancy was obtained. In 2 of the 10 the report of measles was negative. In one there was a history of kidney trouble. In two the history was not asked for. In the remaining five the report is "no history of mea-

sles" or "not known." The majority of cases occurred in 1940 or early 1941. In Gregg's own 13 cases, the history of only 1 was negative. In this case the mother stated that she was kept so busy looking after 10 children that she could not recollect any details of her own health beyond the fact that she was ill at about the sixth week of pregnancy when one of the other children died suddenly from whooping cough. Even though ill, she was unable to go to bed during the last month before the baby was born, one month prematurely. In the great majority of cases the infection occurred either in the first or second month of pregnancy. In a few cases it was in the third month.

Nature of the epidemic in 1940. It was severe and accompanied by complications, and, in the majority of cases in this report, the maternal infection occurred in July or August of this year. Occurring concurrently with this epidemic were epidemics of sore throat emanating supposedly from military camps and spreading to the civilian population. The author questions whether or not the sore throats were streptococcal in origin and the rash diagnosed as "German measles" was a toxic erythema accompanying the streptococcal infection. The description of this rash by the physicians during the epidemic was pleomorphic. Out of 35 cases in which sufficient records are available, the affected baby was the first child in 26 instances, and in three others it was the second child. This notably high incidence in the children of primiparae indicates that the epidemic affected younger people.

Management. Babies should be operated on immediately to permit sufficient light stimulus to reach the retina so that fixation may be developed. If the stimulus is insufficient or delayed, nystagmus will result. The only contraindication to early operation is the general state of the baby's health.

Operation. The anterior chamber is

particularly shallow, and in many cases the very dense central portion of the lens has proved resistant to the needle. Sometimes it has separated off as a firm disc. In others, the whole lens has tended to move away from the point of the needle. In other cases the dissection has been straightforward and easy. Absorption has been slower than that of the ordinary congenital cataract. No opportunity has so far been afforded to examine the fundi of any patient after absorption of the lens matter.

Prognosis. At the present state of our knowledge, we cannot state whether or not other ocular defects are present, or whether they will develop.

REPORT OF COMMITTEE OF NATIONAL HEALTH AND MEDICAL RESEARCH COUNCIL. Under the aegis of the National Health and Medical Research Council, a circular letter was sent by Drs. Swan, Tostevin, Moore, Mayo, and Black to all medical practitioners in Australia to obtain data about children born of mothers who had suffered from exanthemata during pregnancy. When possible, permission was requested to interview the mother and to examine the baby. In the metropolitan area, when a pregnant woman developed rubella or morbilli, it was asked that the investigators be notified so that an interview and examination could be carried out and the child subsequently born examined. If the patient lived in the country, it was requested that data be supplied after the birth of the baby.

Results of the investigation. The mothers were divided into the following groups: (a) those who suffered from rubella during pregnancy, 49 cases; (b) those who had no knowledge of any exanthemata during pregnancy, 4 cases; (c) those who contracted morbilli during pregnancy, 9 cases; and (d) those who suffered from mumps during pregnancy, 2 cases.

Summary. Of 61 infants examined in the course of this investigation, 36 were found to have congenital defects.

Of the 49 mothers who had rubella during pregnancy, 31 of the infants subsequently born exhibited congenital defects. The abnormalities included cataract, deaf-mutism, heart disease, microcephaly, and mental retardation. Eye defects were noted in 14 cases—13 infants had cataracts, of which 10 were bilateral and 3 were unilateral; 1 had buphthalmos. Seven had deaf-mutism; 17 had cardiac abnormalities; all had some degree of microcephaly. With two exceptions all of the 31 mothers with congenitally defective children had contracted rubella within the first three months of pregnancy. The investigators concluded that the disease of the mother was rubella and not a type of streptococcic throat, thought by Gregg to be a possible factor. They were unable, however, to explain why these new complications of what was supposedly rubella asserted themselves unless the virus had altered. The epidemic of German measles in 1940 in Australia was particularly severe, and it may be that this severity was caused by the war and conditions where large numbers of susceptible recruits were herded together in military camps. The disease spread rapidly and the causative agent may have reached a higher stage of virulence. Other investigators have shown that avian and other mammalian embryos show, in contrast to adult tissues, a particular susceptibility to infectious agents. The authors feel that it is logical to assume that the human embryo possesses the same susceptibility to infection that avian and other mammalian embryos do, and that the etiologic factor of German measles, after penetrating the chorionic barrier, is capable of producing severe lesions in the embryo, whereas the same infection in the adult tissues of the mother leads to only minor effects.

From this investigation it is claimed

that when a woman contracts rubella within the first two months of pregnancy, the chances of her giving birth to a congenitally defective child are about 100 percent, and if she contracts rubella in the third month, the chances are about 50 percent.

In a personal communication to the investigators, Gregg stated that all his patients were retarded in their mental growth if not mentally defective. For this and other reasons, Gregg thought that few if any of the children with both eyes affected were likely ever to develop into completely normal children. Other observations in the investigation included the occurrence of deaf-mutism, sometimes with heart disease, of heart disease without other apparent defects, of microcephaly, and of hypospadias.

The investigators concluded with the suggestion that the next step in dealing with this problem should be to isolate the causative agent of rubella with the object of preparing a protective vaccine against the disease. In the meantime, the effect of repeated doses of convalescent serum should be studied not only on mothers in the incubation period of the disease, but also as a prophylactic measure for any pregnant woman who has not previously suffered from rubella. At least this should be done to protect the mother during the first three months of pregnancy.

CASES RECENTLY OBSERVED BY THE AUTHOR

In the past three months the author has had three patients who belong to the group described in the Australian reports.

Case 1. A. S., a girl born at full term without instruments, and weighing 5 pounds and 10 ounces, was examined on the third day because the parents noted a white reflex through the pupil of the right eye. Examination showed a dense,

white cataract occupying the entire pupillary area and preventing any fundus reflex. The pupil was small (from 2 to 3 mm.), and reacted slightly to light. The anterior chamber was shallow. The cornea was clear and the iris appeared normal. The intraocular pressure to palpation was normal. The entire eye seemed somewhat smaller than the fellow eye, and this explained the fact that the right palpebral aperture was narrower than the left. On the fourth day the baby had an attack of cyanosis and was given oxygen. This cyanosis was thought to be due to a congenital heart lesion. There was a murmur over the entire precordium, and X-ray films showed an enlarged heart. No subsequent attacks of cyanosis have occurred. There has been no feeding problem. No microcephaly was present. When the baby was six weeks old, there was a severe conjunctivitis of the right eye causing redness, swelling of the lids, and a mucopurulent discharge. This cleared up in a few days but was followed by high temperature, and meningococci were identified in the blood stream and in four joints. The patient survived this and in one month had an infectious diarrhea which has now cleared up. The baby is now three months old and weighs 7 pounds and 11 ounces. The mother had German measles in the third week of pregnancy. (I am indebted to Dr. Rich Siegel, the child's pediatrician, for data on the general condition.)

Case 2. G. D., a girl, born 12 days early without instruments, and weighing 5 pounds and 15 ounces, had, since birth, a dense white cataract in each eye. No fundus reflex could be seen. The pupils were small and reacted slightly to light. The irides appeared normal. The anterior chambers were very shallow. The corneas were clear. Both globes may have been slightly smaller than normal. Intraocular pressure seemed normal to palpation.

There has been no feeding problem, and the baby has gained weight steadily. No microcephaly was noted. A congenital heart lesion was diagnosed (patent inter-ventricular septum). The baby is now three months old and weighs 9 pounds and 2 ounces. The mother had German measles when four weeks pregnant.

Case 3. T. C., a girl born one week early without instruments, and weighing 4 pounds and 4 ounces had, since birth, a dense, white cataract in each eye. No fundus reflex could be seen. The eyes followed a light stimulus and exhibited a searching or nystagmoid motion. The pupils were 3 mm. in size and reacted sluggishly to light. The irides appeared normal. The anterior chambers were perhaps slightly more shallow than usual. The corneas were small and clear. There was definite microphthalmia of both eyes. The intraocular pressure was normal to palpation. Feeding the baby has been quite a problem, and now, at the age of five months, the weight is 8 pounds and 2 ounces. Microcephaly is present. There is a congenital heart lesion thought to be a patent ductus arteriosus. Other anomalies are mild pyloric stenosis and slight umbilical hernia. The mother had German measles during the first month of pregnancy.

DISCUSSION

All three of the author's patients had congenital cataracts and congenital heart lesions. All mothers contracted German measles within the first month of pregnancy, which was during a rather severe epidemic of German measles in the East,

about one and a half years ago. In the examination, the pupils in these cases were not dilated because the anterior chambers were quite shallow. It was thought that any additional information that might be obtained from mydriasis would not warrant the chances of inducing a glaucoma. Operations will be performed on these patients but they have been deferred for a month or so until the general physical condition stabilizes itself and a better evaluation of the heart condition can be obtained before the general anesthesia is given.

Some imponderables of this subject are: 1. Is the infection of the mother German measles?

2. If it is German measles, then why have we not noted before the occurrence of congenital anomalies in the children so infected?

3. If it is German measles, are the congenital anomalies which are now appearing the result of a more virulent type, or of an altered type, which may have gained access to this country through an increased traffic with Australia?

4. Has the cause-and-effect relation between other infections of the mother in the first three months of pregnancy and congenital anomalies existed in the past, but not been recognized?

5. Can any prophylactic measures be taken to prevent pregnant women from contracting German measles during the first three months of pregnancy?

6. Should pregnant women who contract exanthemata in the first three months of pregnancy be aborted?

THE METABOLISM OF THE CORNEA*

STUDIES ON THE OXYGEN CONSUMPTION OF CORNEAS OF RIBOFLAVIN- AND VITAMIN-A-DEFICIENT RATS

OTIS S. LEE, JR., M.D. AND WILLIAM M. HART, PH.D.†

Iowa City, Iowa

The function of certain vitamin substances as prosthetic groups in respiratory enzymes is now firmly established. An insufficiency of one or of a group of these substances leads to definite pathologic changes in a variety of tissues, including those of the eye. Morphologic changes in the cornea have been cited as specific and pathognomonic of vitamin-A and riboflavin deficiencies. However, the associated metabolic disturbances of this particular tissue have not been studied.

Because of the intimate association between cellular activity and the uptake of oxygen, it is customary to use the measurement of the latter as one index to the rate of normal or altered metabolism. This fact rests on a firm basis, especially in the case of riboflavin, which, in the form of the flavoproteins (d-amino-acid oxidase, xanthine oxidase, cytochromereductase, and others) has an oxidation-reduction potential falling between the pyridine nucleotides and the cytochromes. The function of vitamin A as a prosthetic group in tissues other than the retina has not been shown, but since it obviously has some influence on epithelial structures it will be considered in a similar manner.

Duke-Elder¹ states that the metabolism of the cornea is extremely sluggish. Gundersen,² on the other hand, quoting Bessey's work, claimed that excised corneas of rats showed an astonishingly rapid metabolic rate.

Working with the Warburg respirom-

eter, Bessey³ found that the entire cornea utilizes approximately 4 cubic millimeters of oxygen per hour per milligram dry weight; that is, four sevenths as much as liver tissue, four sixths as much as muscle tissue, and four times as much as cartilage. Kohra,⁴ measuring oxygen consumption of excised rats' corneas with the Warburg manometer, found a high metabolic rate for corneal epithelium. Although he had not demonstrated it experimentally, he nevertheless concluded that the endothelium also has a high metabolic activity. On the other hand, the parenchyma was found to have a low metabolic rate. Orzalesi,⁵ repeating the same experiment, confirmed Kohra's findings.

In the present study, an attempt has been made to correlate the specific morphologic alterations in the cornea (resulting from vitamin deficiency) with changes in the associated respiratory rates. To this end the results are presented in two parts. Part I is a discussion of clinical observations of ocular changes in vitamin-A and riboflavin deficiencies. In part II we present data on the metabolism of the corneal tissues and indicate the possible significance of the findings in the light of associated anatomic changes.

METHODS

THE EXPERIMENTAL ANIMAL

Approximately 200 albino rats from the Sprague-Dawley Institute strain were

* This study, aided by a grant from the John and Mary R. Markle Foundation, was undertaken by Dr. O. S. Lee, Jr., in partial fulfillment of the requirements for a Master's degree in Ophthalmology in the Graduate College, State University of Iowa.

† Now in the Department of Physiology, The Jefferson Medical College of Philadelphia.

used as experimental animals. These rats were of both sexes and from 19 to 21 days of age when placed on the special diets.

Sixty rats were placed on a riboflavin-deficient diet and 25 rats on a vitamin-A-deficient diet. The remainder were fed on a control diet and allowed to grow to about 60 to 80 gm. in weight, when they were used for studies of normal corneas.

The rats were placed in individual cages with raised screen floors to prevent access to their own excreta. Tap water was given *ad libitum*.

THE DIET

A. Riboflavin-deficient diet. Two types of diet were used. Thirty rats were given Diet no. 1 and another 30 Diet no. 2.

Diet no. 1

	percent
Casein (vitamin free, Labco)	15
*Salt mixture (Hubbell no. 351)	2
Cod-liver oil	5
Sucrose	15
Corn starch (extracted with alcohol)	47
Crisco	14
Cellophane (ground)	2

One vitamin-B-complex pill of the following composition was given to each rat daily:

	mg.
†Thiamine chloride	0.04
†Nicotinic acid	0.20
†Ryzamin B	50.0
Sufficient alcohol-extracted cornstarch to make pill mass.	

For the control diet, 0.04 mg. of riboflavin was added to the pill.

Diet no. 2

(For one kilogram diet, enough to last 20 rats 7 days)

Casein (vitamin free, Labco)	200.0 gm.
------------------------------	-----------

* Hubbell, R. B., Mendel, L. B., and Wake-man, A. J. A new salt mixture for use in experimental diets. *Jour. Nutr.*, 1937, v. 14, pp. 273-285.

‡ Burroughs Wellcome & Company.

Sucrose	362.0 gm.
Cerelose	362.0 gm.
Salt mixture (Hubbell no. 351)	25.0 gm.
Cellophane (ground)	30.0 gm.
Cod-liver oil	20.0 gm.
†Choline chloride	1.0 gm.
†Thiamine chloride (Betabion)	3.0 mg.
†Pyridoxine hydrochloride (Hexabion)	3.0 mg.
†Pantothenic acid, Ca salt	10.0 mg.
†Nicotinic acid	50.0 mg.
†Alpha-tocopherol (ethyl laurate)	6.0 mg.
Para-aminobenzoic acid	100.0 mg.
Inositol	100.0 mg.

A week's supply was made at one time and kept in the ice box. If kept for longer periods or at room temperature, there is a reduction in thiamine potency.

In the control diet, riboflavin** (2 mg.) was added to the above mixture. Approximately five grams of food were eaten by each rat daily. The rats responded to the two riboflavin-deficient diets in practically the same manner. The second diet, however, was preferred because of its synthetic composition.

B. Vitamin-A-deficient diet**

	percent
Casein (vitamin free, Labco)	20.0
Glucose	67.5
Salt mixture (Hubbell)	2.5
Cellophane (ground)	3.0
Spry (hydrogenated cotton-seed oil)	2.0
Brewers' yeast, Harris	5.0
Viosterol (Abbott's)	0.2 c.c. per kilogram

PREPARATION OF CORNEAL TISSUES

A. Removal of cornea from the eyeball. The rats were killed by a blow to the occipital region. While the eyeball was held with a pair of fixation forceps, an initial incision was made by introducing a fine curved bistoury into the anterior chamber, after which the section of the cornea was completed with iris scissors. Care was taken to confine the cut to the limbus and not to include any scleral tissue. This precaution was necessary to

** A modification of the vitamin-A-deficient diet for rats given in the U. S. Pharmacopeia, Eleventh Decennial Revised, p. 479.

prevent inclusion of iris and ciliary-body tissues with the cornea.

B. Removal of corneal epithelium. In experiments in which studies on the corneal epithelium and stroma were to be made separately, the epithelium was removed from the cornea of the intact eyeball by the following method: The globe was immobilized, and with a corneal spud the epithelium was scraped off carefully from the periphery to the center. With practice and reasonable care a complete sheet of epithelium was obtained by this method. This technique was checked by histologic studies and found to be satisfactory. After removal of the epithelium, the cornea was excised by the method previously described.

C. Removal of endothelium. An attempt was made to remove the endothelium for study but it was found impossible to obtain sufficient tissue for determination of oxygen uptake.

Both corneas from each rat were used in every experiment, and the tissues were placed at once in the respirometer cups which contain 0.5 c.c. modified Locke's solution.* In studies on isolated epithelial tissue it was found necessary to exercise care to keep the sheet of epithelium from folding on itself and thus preventing adequate contact with the substrate.

MEASUREMENT OF OXYGEN CONSUMPTION

Oxygen uptake was determined by use of six Barcroft micro-differential manometers which had been calibrated in

* The medium had the following composition (expressed as percent of the anhydrous salt)

NaCl	0.7
KCl	0.035
CaCl ₂	0.025
MgCl ₂	0.010
Na ₂ SO ₄	0.025
glucose	0.075
Sorensen phosphate buffer (M/15) pH 7.4, 7.5 ml. per 100 ml.	

the usual manner. Redistilled kerosene colored with Sudan III was used in the manometers. The manometer vessels were of approximately 5 cubic centimeters' capacity.

In all experiments each of the six vessels contained corneas or epithelial tissues from two eyes and 0.5 c.c. of the modified Locke's solution. The six compensating vessels contained enough of the same solution to make the fluid volume uniform. Each central well or cup of the respirometer vessels contained a roll of filter paper and approximately 0.1 c.c. of 20-percent potassium-hydroxide solution to absorb carbon dioxide.

The respirometers were mounted on a shaking device, similar to that described by Dixon,⁶ having a rate of 60 cycles per minute with an amplitude of 2.5 cm. in a water bath whose temperature was 39° C. Measurement of oxygen uptake was begun at the end of a 20-minute equilibration period. Readings were then taken at 10-minute intervals for one hour. Results are given in cubic millimeters of oxygen (N.T.P.) per cornea.

The rate of oxygen uptake was invariably independent of the rate of shaking. When the manometers were gassed with oxygen, the results were not different from ungassed-manometer values. Therefore, diffusion was shown to be adequate with the technique used.

All calculations were made on the basis of corneal units rather than gram-weight units. This was done because of the very slight weight of the cornea and because this weight was quite constant (an average of 0.9 mg. dry weight per cornea for rats weighing around 70 grams). It is also obvious that the small mass of epithelium did not lend itself to accurate weighing. Since this is a comparative study between the metabolic activity of normal cornea and corneas of vitamin-A- and riboflavin-deficient rats

rather than a comparison of oxygen consumption of cornea with other tissues, the present method of expression of results was considered to be adequate.

In order to permit a relatively accurate comparison between the oxygen uptake of normal and pathologic corneas on a unit-cornea basis, rats with normal corneas were taken for study when approximately 70 grams in weight. This weight was found to be similar to that of rats on vitamin-A- or riboflavin-deficient diets when they developed pathologic changes in the cornea.

RESULTS

PART I. CLINICAL OBSERVATIONS OF OCULAR CHANGES

RIBOFLAVIN-DEFICIENT RATS

Ocular signs of deficiency were first observed after five to seven weeks. The palpebral fissures became narrowed and the eyeballs appeared sunken in the orbits. The lids were edematous and there was a loss of hair about the lid margins. These changes were followed soon by the appearance of a serosanguineous fluid in the conjunctival sac, which resulted in crusting of the lid margins and at times in complete sealing of the lids. The initial corneal change was not vascularization as observed by Bessey and Wolbach,³ Johnson and Eckardt,⁷ and others, but rather a fine, sandy roughening of the epithelial surface demonstrable with focal illumination. After staining with 1-percent fluorescein solution, observation with a loupe or corneal microscope revealed fine stippling of the corneal surface. This usually occurred after the seventh or eighth week, and was accompanied by engorgement of the limbic vascular plexus. After an additional 7 to 14 days, beginning vascularization of the cornea was observed. The appearance of vascular loops and the manner of their extension into the corneal stroma compared with the excellent

and detailed description given by Bessey and Wolbach.³ Gross corneal ulcers were noted in approximately 10 percent of the rats with vascularization of the cornea; the ulcers were superficial, perforation did not occur, and there was no massive sloughing of corneal tissue. Most of the animals were sacrificed for respiratory studies after corneal vascularization. In the few that were kept for further observation, the only additional corneal changes were an increased scarring of the tissue and some regression of the corneal vascularization. These animals usually did not live longer than two weeks after vascularization was first noticed.

VITAMIN-A-DEFICIENT RATS

The earliest manifestations were slight photophobia, lacrimation, and reddening of the conjunctiva which usually began during the third week of experiment. Shortly thereafter, the normally prominent protruding eyes appeared to recede into the orbit, with exaggeration of the aforementioned signs. A serosanguineous secretion developed. No changes were observed in the cornea until the fourth to sixth week, when a haziness was noticed, particularly about the periphery. The surface became dry, lusterless, and oily, and normal transparency was lost. The epithelial surface, however, remained intact, and no staining occurred with fluorescein. The degree and extent of the xerotic condition increased daily, and if the animal survived, keratomalacia usually developed within a week after the initial appearance of definite xerotic changes. With the appearance of keratomalacia, progression was extremely rapid, and in 24 to 48 hours, the cornea sloughed away in part or *in toto* and perforation followed. Examination of the corneas during the stages of xerosis failed to reveal the presence of vascularization. However, after the onset of kera-

Fig. 1 (Lee and Hart). Normal rat cornea ($\times 350$).

tomalacia, vascularization was seen. A conspicuous feature of the pathologic changes was the remarkable vitality of the corneal epithelium, for it remained intact throughout the stages of xerosis. Even when necrosis of the stroma was taking place in beginning keratomalacia, the anterior epithelium was often preserved. This observation has been previously reported by Yudkin and Lambert.⁸

PART II. METABOLISM OF THE CORNEAL TISSUES

NORMAL CORNEA

The assumption sometimes made that the metabolism of the corneal epithelium is slow and contributes little to the metabolism of the intact cornea is not supported by the observations made in these studies, nor is it in accord with the observations of the rapid regeneration of corneal epithelium following injury. The results of

the experiments here presented reveal that the oxygen uptake of the epithelium is rapid, for comparative studies show that the normal epithelium takes up the major portion of oxygen consumed by the excised intact normal cornea, whereas the stroma is relatively inactive (tables 1 and 2). The actual ratio of oxygen consumption between the stroma and epithelium is considerably greater than is shown in table 2, for these determinations were made on the basis of corneal units rather than on gram equivalents.

A comparison of table 1 with table 2 shows that the total oxygen consumption of the separated epithelium and stroma does not approximate that of the intact cornea. This discrepancy is to be expected, since there is some damage to the epithelial cells during the process of denudation. The technique used was at best relatively crude but still was superior to

other methods that were tried.

Since the endothelium consists of a single layer of cells on the posterior surface of the cornea it was found impossible to demonstrate its oxygen uptake with the present technique and instruments. Therefore, conclusions concerning the metabolic activity of the endothelium cannot be made at this time.

CORNEA OF RIBOFLAVIN-DEFICIENT RATS

In respiratory studies on vascularized corneas from riboflavin-deficient rats, it was found that the oxygen uptake of such corneas when intact was nearly the same as that of normal controls (table 3). Separate studies on the epithelium, however, showed its oxygen consumption to be markedly depressed, whereas the oxygen consumption of the vascularized stroma was much higher than that of normal corneal stroma (table 4). Further experiments revealed that if corneas were taken when epithelial damage only could be demonstrated and no pathologic change in the stroma was yet evident, the oxygen uptake of the epithelium continued to be low whereas the oxygen uptake by the stroma approximated that of the normal

controls (table 5).

Since histologic studies of corneas of riboflavin-deficient rats demonstrated that the first change to take place in the eyeball is swelling and necrosis of the corneal epithelium (fig. 2), it would be logical to infer that the decrease in oxygen

consumption of the epithelium was the result of the cellular destruction. The changes that follow damage to the epithelium consist of newly formed blood vessels which invade the stroma and are accompanied by cellular infiltrations (fig.

3). The presence of these cellular elements, which are absent in the normal avascular cornea, probably accounts for the increase in oxygen consumption observed in riboflavin-deficient corneas.

CORNEA OF VITAMIN-A-DEFICIENT RATS

In the experiments on xerotic corneas, the oxygen uptake of the entire corneas was the same or even higher than that of the normal controls (table 6). The oxygen utilization of the epithelium alone showed it to be in many cases higher than that of the normal corneal epithelium. The stroma, however, was found to be comparable to that of normal stroma in its relatively low metabolic activity (table 7). These findings are in accord with the results of Orzalesi,⁵ who found the respiratory rate and glycolytic activity of vitamin-A-deficient corneas of rats to be more active than those of normal controls.

Fig. 2 (Lee and Hart). Cornea of riboflavin-deficient rat with early changes in the epithelium ($\times 400$).

Fig. 3 (Lee and Hart). Cornea of riboflavin-deficient rat with more advanced changes in the epithelium and vascularization with infiltration in the stroma ($\times 450$).

He attributed this to the marked necrotic changes in the tissue which might free certain substances capable of accelerating metabolism.

The metaplasia and hyperlasia of the corneal epithelium represent the first manifest pathologic change in the eyeball of rats on a vitamin-A-deficient diet (fig. 4). Most of the corneas used in the pres-

ent experiments were taken when the pathologic change was confined to the corneal epithelium and no changes were found macroscopically or microscopically in the deeper tissues. Therefore, the retention of approximately normal oxygen consumption of such corneas may be due to the absence of any damage to the vitality of the cells themselves, while even

higher oxygen uptake could be ascribed to the cellular hyperplasia that has taken place in the epithelium. When more complete keratinization of the epithelium had occurred, vascularization of the stroma was observed. New blood-vessel formation usually is associated with necrosis and cellular infiltration of the stroma (fig. 5). These changes representing an ad-

vanced stage of the vitamin-A deficiency rapidly result in complete sloughing of the tissues and rupture of the cornea.

Figure 6 is a composite chart which gives a graphic view of all the data on oxygen consumption.

COMMENT

There has been no clear-cut demon-

* In experiments in which nonvascularized corneas were used, only those eyes which showed a diffuse haziness of the epithelial surfaces were taken. These corneal changes represented the earliest manifestations observed in riboflavin deficiency of rats and consisted of edema and necrosis of the epithelial cells, as illustrated in figure 2.

stration of the sequence of changes occurring in the eye in the vitamin deficiencies in question. Indeed most authors have not seen the need for making such observations. Nevertheless, this consideration may have the utmost importance in the attempt to unravel the physiologic changes involved in vascularization. With regard to riboflavin deficiency in the rat, Bessey and Wolbach³ state that capillaries grow into the cornea from the limbus after the fourth week. Quoting from their paper, "This happens before any change in the cornea visible in the gross has taken place. The transparency is undiminished. While these vessels may be seen by slitlamp illumination, no turbidity of the cornea or change in the corneal epithelium is revealed by this method or by histological study." And from the same paper with regard to vitamin-A deficiency: "We are disposed to disregard the inflammatory explanation of vascularization. Always,

* The corneas used in these experiments were in various stages of xerosis. The xerotic process, however, was in all cases grossly visible to the unaided eye. A few of them showed beginning keratomalacic change in the stroma, as evidenced by an early necrosis of the stromal fibers on histologic study. However, no corneas with softening of the cornea visible macroscopically nor those in which perforation had taken place were used.

however, the presence of capillaries in the cornea was accompanied by a characteristic change in the corneal epithelium, indicative of the shift to a keratinizing

Fig. 5 (Lee and Hart). Cornea of vitamin-A-deficient rat with more advanced changes in the epithelium and vascularization with infiltration in the stroma ($\times 400$).

hyperplasia. The speculation is warranted that an important factor in causation may be a change in permeability of the epithelium in its effect upon respiration of the cornea as a whole."

These authors postulate a functional change rather than a change in the morphology of the epithelium to account for the ingrowth of vessels. Wolbach and Howe⁹ had previously observed that in

* See footnote, table 6.

vitamin-A deficiency vascularization of the cornea followed keratinization of the epithelium and postulated that the response was due to greater physiologic demands from active and changed epithelium. In the later work, Bessey and Wolbach³ reviewed the same material and, finding certain similarities to their observations in riboflavin deficiency, decided that vessel ingrowth occurred concurrently with the epithelial changes. This order of events apparently appeared to the authors to preclude an "inflammatory" explanation of vascularization. It would be difficult to criticize the inflammatory hypothesis since the mechanism of such a reaction is entirely unknown, nor is it altogether clear what is meant by a "change in permeability."

A variety of possibilities might be drawn upon in developing a logical explanation for vascularization of the cornea under these conditions. The suggestion offered by Bessey and Wolbach that vascularization is a response to asphyxia of the tunica propria has merit in that it suggests a new tack for further work, and indeed constituted the chief stimulus for the present endeavor.

At present we may safely assume some intimate relationship between the epithelium and the stroma, but the fundamental mechanisms are still obscure and no simple explanation can dispose of the problem. It is a significant fact that in our

experiments, vascularization of the corneal stroma in both riboflavin- and vitamin-A-deficient rats is preceded by a morphologic change in the epithelium.³

SUMMARY

1. The normal epithelium of the cornea is shown to have a high oxygen uptake in contrast to a low uptake by the stroma. Because the endothelium consists of only a single layer of cells, it was impossible to measure its oxygen consumption by this method.

2. The oxygen uptake of the corneal epithelium of riboflavin-deficient rats was found to be lessened. This may be accounted for by the cellular necrosis present in the epithelial cells of such corneas. When vascularization was present, the oxygen uptake by the stroma was found to be elevated, whereas in the absence of vascularization the oxygen uptake remained low. It is reasonable to assume that the increased oxygen uptake by the stroma is the result of vascularization and cellular infiltration.

3. The metabolic activity of the xerotic cornea was found to be normal or higher than normal. The presence of metaplasia and hyperplasia instead of an actual cellular destruction of the corneal epithelium may be responsible for the approximately normal oxygen consumption of corneas of rats with vitamin-A deficiency.

THE USE OF TYROTHRIN, A BACTERIAL EXTRACT, IN THE TREATMENT OF MARGINAL ULCERS OF THE CORNEA*

SYLVAN BLOOMFIELD, M.D.

New York

In 1939, Dubos¹ reported the isolation, from bacterial culture, of a substance that destroyed gram-positive cocci. This antibacterial extract was tyrothricin; it was prepared from cultures of the *Bacillus brevis*, an aerobic sporulating saprophyte commonly found in sewage and soil.^{2, 3} Tyrothricin is a stable mixture of gramicidin and tyrocidine, both of which can be crystallized, with some difficulty, from the mother substance.⁴ The antiseptic effect of tyrothricin is principally due to its content of gramicidin. Because of its greater stability and relative ease of preparation, tyrothricin is the substance preferred for clinical use.⁵

Gramicidin is a polypeptide that has been shown to inhibit the growth of gram-positive cocci.⁵ Although this bacteriostatic action varies in effectiveness against different strains of these microorganisms, it is, in general, highly effective in even minute dosage of the drug.⁶ Meningococci and gonococci are also inhibited by gramicidin, though to a lesser degree, whereas other gram-negative microorganisms have proved invulnerable to this substance.⁵ It has been further shown that the presence of gram-negative bacilli interferes with the bacteriostatic action of gramicidin, so that it is quite ineffective against mixed infections. The drug is also inactivated by cephalin.⁵ Gramicidin has been shown

to be slightly hemolytic,⁷ a property which can be inhibited by small amounts of glucose or mannitol.⁵

Tyrocidine, which comprises 80 percent of the tyrothricin mixture, is a protoplasmic poison equally effective *in vitro* against gram-positive and gram-negative organisms.³ *In vivo*, however, its action is largely destroyed by serum; it therefore contributes little to the effectiveness of tyrothricin as an antiseptic. The hemolytic and leucocytolytic effects of tyrothricin in large dosage have been attributed to its content of tyrocidine.⁷

Tyrothricin is soluble in alcohol and acetone but not in water or body fluids. It is also very poorly diffusible. Because of these physical properties and the toxicity of its component tyrocidine, tyrothricin is not employed systemically.^{7, 8} However, its poor absorbability and highly potent bacteriostatic action in small dosage renders it a safe and very effective antiseptic against gram-positive organisms by topical administration or the irrigation of infected body cavities.⁹

The conjunctival sac presents a surface prone to infection with gram-positive organisms, especially staphylococci, streptococci, and pneumococci. Moreover, it is easily treated by topical application without danger to the body by absorption of the medication into the general circulation in any appreciable quantity. It was therefore thought that in infections of the ex-

*From the ophthalmological service of Dr. R. K. Lambert, The Mount Sinai Hospital.

ternal eye and associated structures a favorable opportunity is provided for the therapeutic trial of tyrothricin.

Because of the greater availability of the more widely used antiseptic agents, and their usual efficacy in the treatment of the common infective conjunctivides, no attempt was made at this time to treat such cases with tyrothricin. However, several patients with stubbornly resistant marginal ulcerations of the cornea were brought to the hospital and these afforded an opportunity for a therapeutic test of this drug.

Marginal ulcers of the cornea are not uncommon. The most frequent type is that associated with the more severe catarrhal conjunctivides. In these cases the keratitic complication is considered an extension of the septic process in the conjunctiva. Treatment of the conjunctivitis with any of the usual antiseptics, occasionally supplemented by cauterization of the corneal lesion, usually results in rapid healing of the ulcer.¹⁰

There is another group of marginal corneal ulcers, more common in old people, that occurs without apparent cause, and is not associated with conjunctival inflammation.¹¹ These arise as marginal, subepithelial infiltrates which coalesce and break down to form superficial erosions crescentic with the limbus. Local ciliary injection is usually present, but very little general conjunctival reaction occurs. Such superficial ulcers usually heal readily when antiseptic applications or cauterization and pressure dressings are employed. However, they not infrequently prove quite resistant to such measures, and persist with distressing symptoms of photophobia, lacrimation, and pain.

Four instances of superficial marginal ulcerations of the cornea, not associated with conjunctivitis, and resistant to the usual forms of therapy, were recently

treated with tyrothricin at this institution. An alcoholic solution of the latter was suspended in distilled water in a concentration of 0.2 mg. per cubic centimeter. An ointment was also compounded consisting of tyrothricin in a petrolatum-lanolin base, in the same 1:5,000 concentration. Such extreme dilution had previously proved effective against infection in other areas,⁹ and it eliminated the possibility of absorption in any quantity sufficient to cause toxic reactions. Instillation of these preparations in the eyes of rabbits and normal volunteers proved their innocuousness; subsequent therapeutic applications in numerous cases have failed to reveal any local or systemic toxic reaction.

Case 1. A. S., a man, aged 67 years, presented himself in the Out-Patient Department with the complaint of having had pain in the right eye for several days. Examination disclosed a staining marginal ulcer of the cornea of the right eye, with local ciliary injection. There was no evidence of associated conjunctivitis. Cultures of material taken from the corneal ulcer were reported to show the presence of *Staphylococcus aureus* A and *Staphylococcus albus* B. The left eye appeared to be normal.

A 1-percent solution of silver nitrate was applied to the lower lid of the right eye; a drop of 20-percent argyrol was prescribed to be instilled three times daily, and bichloride of mercury 1:5,000 to be instilled in the right eye each night. After five days on this regime the corneal ulcer was found to have increased in size crescentically. It was then cauterized with tincture of iodine and instead of the previously prescribed medication 5-percent-sulfathiazole ointment was instilled three times daily. Five days later the ulcer was found to be larger, and the regional ciliary vessels were more engorged. A pressure

dressing was applied but after several days no evidence of healing was seen. Mercurochrome 1 percent was instilled into the eye three times daily for five days thereafter, with no satisfactory results. The actual cautery was applied to the ulcer, but there was no apparent reduction in the size of the lesion. For 10 days thereafter the patient was treated only with 5-percent sulfathiazole ointment instilled into the right eye three times daily. During this period the staining lesion persisted unchanged and the patient's pain, lacrimation, and photophobia were very distressing.

Since routine methods had failed, the patient was instructed to apply one drop of the tyrothricin suspension to the surface of his affected eye every three hours, and to discontinue all other medication. After three days of application it was found that the ulcer was much smaller, ciliary injection much less marked, and the patient was greatly improved symptomatically. On the ninth day after tyrothricin therapy had been instituted no further staining of the cornea was present and the patient was considered cured. The region of the erosion presented a translucent superficial scar with no ciliary injection.

Case 2. R. L., a housewife, aged 58 years, appeared in the clinic complaining of lacrimation and pain in both eyes for two days. Examination disclosed small marginal infiltrates just within the nasal limbus of the left eye and similar lesions temporally in the right. There was some local ciliary reaction but no general conjunctival injection. One-percent atropine was instilled in each eye and 5-percent sulfathiazole ointment was prescribed for application three times daily, to be followed by hot compresses. After five days of this regime the infiltrates in the cornea of the left eye had disappeared, but those

in the right persisted. One drop of 20-percent argyrol was then advised for the right eye, to be instilled every four hours. After two weeks, the infiltration had involved the entire limbal circumference and marked circumcorneal hyperemia was noted. In addition, just within the limbus inferiorly, two staining superficial ulcers were seen. Cultures of material taken from these erosions yielded *Staphylococcus albus* B. Bichloride-of-mercury ointment 1:5,000 was instilled and a pressure dressing applied repeatedly. One week later the ulcerations were larger. Cauterization of these lesions was performed with tincture of iodine, and pressure dressings were applied on two occasions during the following week, but induced no improvement. Three days later the ulcerations had coalesced across the lower corneal margin in crescentic fashion. Trichloroacetic-acid cauterization was done, 5-percent sulfathiazole ointment instilled, and pressure dressing applied again. Two days later no improvement was noted.

At this point, after six weeks of therapy with the aforementioned agents, tyrothricin was prescribed. One drop of the suspension was ordered applied to the affected eye every three hours and tyrothricin ointment placed in the conjunctival sac at night. Three days later a diminution in the marginal infiltration and the ciliary injection was noted. The staining lesions of the lower corneal margin were definitely smaller and symptomatic relief was marked. Improvement continued uninterruptedly, and after two weeks of tyrothricin administration no further ulcer remained, the submarginal infiltrates had disappeared, and circumcorneal injection was minimal. At the site of the ulcer there remained a depressed white scar with slight peripheral vascularization.

Case 3. L. C., a woman, aged 72 years,

had undergone several epilations for trichiasis subsequent to an old trachomatous process of both upper lids. She presented herself at the clinic complaining of unusual pain, lacrimation, and photophobia in the left eye. Examination disclosed a marginal crescentic staining ulceration with ciliary injection at that point but no evidence of conjunctivitis. No cilium that might be irritating the cornea could be found on the lids at this time. A drop of 1-percent atropine sulfate solution was administered, 5-percent sulfathiazole ointment instilled into the conjunctival sac, and a pressure dressing applied. Two days later the lesion was larger and the patient's symptoms worse. The patient was then given tyrothricin solution to be instilled in the dose of one drop every three hours and the tyrothricin ointment was ordered applied nightly. Symptomatic improvement was rapid, and three days later the area of the staining lesion was noticeably smaller. After eight days the patient was completely cured and only an epithelized scar remained at the site of the ulcer.

Case 4. A. K., 45 years of age, presented a history of recurrent marginal corneal ulcerations. These previously had responded in a few days to local antiseptic therapy. On this occasion a staining erosion of the lower corneal margin of the left eye, not associated with conjunctivitis, had resisted treatment with 20-percent argyrol, sulfathiazole ointment, and repeated pressure dressings for 10 days. Cultures of the ulcer were taken twice, but no growth occurred, possibly due to antiseptics previously used. One drop of the tyrothricin suspension was instilled into the conjunctival sac every three hours, and all other medication stopped. The ointment was not employed after one application because the patient thought it irritating. After three days of this regi-

men symptomatic improvement was notable; on the fifth day ciliary injection had disappeared, and no further staining of the lesion could be seen.

COMMENT

The etiology of these primary superficial ulcerations of the marginal cornea is unknown. Fuchs¹² in 1893 considered them as a complication of the gouty diathesis. Duke-Elder¹¹ associates some with rosacea, but believes that most cases originate in a remote septic focus with metastatic corneal involvement occurring through the marginal vascular plexus. Whatever the cause, it seems very probable that infection, either primary or secondary, may be a factor in the persistence of the lesion and one against which active treatment is indicated. Where the more easily available antiseptics prove futile, tyrothricin appears to be a very effective therapeutic agent in this condition.

Since tyrothricin is now commercially available, the range of its clinical applicability deserves investigation. Studies are now under way to determine its effectiveness in other diseases of the eye. Further trial will be necessary to confirm our favorable impression of this apparently safe and extremely effective new antibacterial agent.

SUMMARY

1. Tyrothricin* of Dubos has proven an effective antiseptic agent against gram-positive organisms.
2. It may be readily and safely applied to the conjunctival sac in effective concentrations.
3. Four cases of resistant marginal ulcers of the cornea are described in which tyrothricin was employed with gratifying results.

*Tyrothricin is marketed by Sharp and Dohme, Philadelphia, Pennsylvania.

EXOPHTHALMIC OPHTHALMOPLÉGIA*

REPORT OF A CASE WITH THYROTOXICOSIS OF UNUSUALLY LONG DURATION

I. D. FAGIN, M.D., R. W. PAGEL, M.D., AND
H. H. SAND, M.D.
Detroit 15, Michigan

Although somewhat more than 100 cases of exophthalmic ophthalmoplegia have been reported,¹ the syndrome still remains a clinical rarity. The causes of the exophthalmos and of the ophthalmoplegia, and the relationship of these ocular dysfunctions to disturbances of thyroid metabolism, are still unclear. Autopsy reports of cases of exophthalmic ophthalmoplegia are very rare; and it is for the purpose of adding to the available data for eventual clarification of this interesting entity that the following case history with the findings of post-mortem examination is reported. The case is of further medical interest because of the unusually long duration of symptoms of thyrotoxicosis, and their variability.

CASE HISTORY

A. E. S., an unmarried white man, 55 years of age, and a butcher by occupation, was admitted to the U. S. Marine Hospital on June 30, 1942, complaining chiefly of generalized weakness of four months' duration.

* From the United States Marine Hospital.

Family history was irrelevant; there was no knowledge of thyroid dysfunction or organic disease of the nervous system occurring in any close relative.

The *past history* included uncomplicated mumps, measles, chicken-pox, and scarlet fever in childhood; lymphangitis of the right forearm in 1918, resulting from infection of a laceration of the right hand; pneumonia in 1928, with uneventful recovery; and a cholecystectomy in 1932, performed because of gastrointestinal disturbances and roentgenologic evidence of a nonfunctioning gallbladder. There was no history of syphilis, or encephalitis, or cerebral trauma.

History of present illness. The existence of detailed records of medical examinations of the patient (records of examinations for insurance, for determination of disability claims, and for war-pension purposes) facilitated the accurate formulation of the clinical course, and the following data were derived from these records and from the patient's story.

In 1913, the patient first became aware of a "goiter," which manifested itself only

as a slightly uncomfortable, diffuse swelling of the suprasternal portion of the neck until 1916, at which time nervousness associated with emotional instability developed. In 1918, the patient was drafted into the United States Army, but the development of exertional dyspnea and palpitation rendered him unfit for military service and he received a medical discharge after less than three months' service. The discharge diagnosis was hyperthyroidism. At that time (1918) *both* lobes of the thyroid were moderately enlarged, but exophthalmos was not present. The heart was not enlarged, a soft apical systolic murmur being the only cardiovascular abnormality noted.

Following his discharge from the Army, the patient continued to be disturbed somewhat by nervousness, episodes of palpitation, and a tremor of the hands, and in July, 1921, he noticed moderate weakness of both arms associated with a sense of numbness in the fingers, and weakness of grip. In August, 1921, physical examination revealed symmetrical enlargement of *both lobes* of the thyroid gland. The heart was just within normal limits in size; a precordial heave and a palpable thrill at the apex were present. There was a loud, blowing, systolic murmur at the apex which was not transmitted. One examiner also described a very indistinct short presystolic apical murmur which, however, was not heard by other examiners. The pulse rate was 90 beats per minute, and the response to exercise was normal. The blood pressure was 135/95. Ptosis of the left upper lid and a left divergent strabismus were present. The left eye was more prominent than the right. The diagnosis made was exophthalmic goiter.

The patient's vision seemed to become impaired somewhat, and intermittent diplopia, headache, and blurring of vision developed in September, 1921. Physical

examination in November, 1921, revealed exophthalmos, ptosis of the left upper lid, and a left divergent strabismus. The visual acuity was 20/20 in the right eye and 20/40 in the left eye. Examination of the fundus showed obliteration of the physiologic cups of the nerve heads, without definite papilledema, and engorgement of the retinal veins. The heart was definitely enlarged to clinical examination, but the blood pressure was normal (108/76), and there were no irregularities in rhythm and no murmurs. The muscles of the arms were soft and flabby. The patellar reflexes were exaggerated. Romberg's sign was not present, and the sensory status was normal. The face was rather expressionless and immobile. Wassermann tests on the blood and spinal fluid were reported as "doubtful positive" from a city laboratory, but as negative from a larger state health laboratory. The colloidal gold curve was 0000000000, and the cell content of the spinal fluid was normal. Urinalysis revealed no abnormalities. The basal metabolic rate was then plus 24 percent. The examiners at that time suggested that the patient's difficulties might be due to a basilar meningitis or a brain tumor.

Three months later (in February, 1922) because of persistence of weakness of grip, clumsiness of hands, and the development of some difficulty in walking which he attributed to weakness, the patient again sought medical advice. The positive findings of physical examination then were enlargement of the *left* lobe of the thyroid gland; hyperactive deep reflexes, particularly marked in the patellar reflexes; weakness of the hands and arms, with greatly impaired ability to dorsiflex the hands and elevate the arms; positive Babinski sign bilaterally; slight labial ataxia; exophthalmos; external strabismus; and right hyperphoria. The heart and lungs were considered normal. Re-

sults of a urinalysis, blood count, blood Wassermann test, and X-ray examination of the skull were not abnormal. The diagnosis suggested by the examiners at that time was amyotrophic lateral sclerosis, but it was not substantiated by the subsequent course.

The muscular weakness of the extremities apparently subsided spontaneously, but the enlargement of the thyroid, the exophthalmos, and the nervousness persisted. Examinations in 1924 and in 1925 indicated that the *left* lobe of the thyroid remained more enlarged than the right. Von Graefe's sign and Moebius's sign were present, in addition to the exophthalmos, but the eyeball movements were normal. The ptosis was not evident at that time.

In 1926, the eyes were reported *entirely normal* by a competent ophthalmologist; there was no exophthalmos, no ptosis, no strabismus, no abnormality in the fundus. The patient's basal metabolic rate that year ranged about plus 5 percent, and a note was made that there was no clinical evidence whatsoever to indicate thyrotoxicosis, and that examination of the nervous system was entirely negative for evidence of gross organic disease. By 1930, even the enlargement of the thyroid gland and the tremor had disappeared, and the patient considered himself in relatively good health, although exophoria of the left eye had developed.

In 1932, while the patient was recuperating from the cholecystectomy, ptosis of the right lid developed gradually over a period of about one month, and ptosis of the left lid developed two months later. The bilateral ptosis persisted, and the patient elevated his lids with adhesive tape strapped to the forehead. The exophthalmos recurred, and the *right* lobe of the thyroid gland became enlarged. Tremor and hyperactive deep reflexes were again noted. The presence of these

features, plus tachycardia and dermographia, prompted the attending physicians to return to the diagnosis of hyperthyroidism.

In 1938, the patient noticed the recurrence of generalized weakness, but he remained ambulant. In 1940, transient blurring of vision and diplopia occurred and spontaneously subsided. Exertional dyspnea and palpitation again developed, but there was no orthopnea, ankle edema, or precordial pain.

Since February, 1942, the patient had noticed that his weakness was becoming more pronounced; his voice became weak and hoarse, and ingested food was sometimes regurgitated through the nose. There had been a gradual weight loss of 47 pounds since 1924. These difficulties persisted, and the patient presented himself for admission at the U. S. Marine Hospital on June 30, 1942.

PHYSICAL EXAMINATION. The patient was an elderly white male, fairly well developed but in a poor nutritional state, appearing chronically ill; height 65 inches, weight 115 pounds. Orientation in time, place, and person was accurate, and there was no discernible impairment of judgment or insight. Anxiety, general somatic hypermotility, and a coarse tremor of the fingers and tongue were apparent.

Ocular examination. Moderate bilateral exophthalmos and complete bilateral ophthalmoplegia externa (including the levators palpebrae superioris) were present (fig. 1). The distance from the external canthus to the apex of the corneal surface was 18 mm. on the right, and 19 mm. on the left, by gross measurement. (Exophthalmometric determinations were not available.) There was no eyeball motion whatsoever. Slight edema of the lower lids was evident. The patient elevated his upper lids with adhesive tape attached to the forehead, in order to counteract the

ptosis. Ophthalmoscopic examination of the fundi was negative, the discs, vessels, and retinas appearing normal. Pupillary reactions were normal. The visual acuity was 20/20 in each eye. Determination of perimetric field vision indicated a very slight contraction of the visual fields. The patient was not aware of the paralysis of eyeball motion.

Trunk. The neck veins were dilated but

base. The rhythm was wholly irregular, auricular fibrillation, and there was a pulse deficit of 34 beats per minute (ventricular rate 154 per minute, pulse rate 120 per minute). The blood pressure was 148/80.

The abdomen was normal except for a long right rectus scar covering a small incisional hernia. The extremities, genitalia, and rectum were normal.

Fig. 1 (Fagin, Pagel, and Sand). Anterior and lateral photographs of the patient reported, demonstrating an enlargement of the thyroid, the ptosis, and the exophthalmos (partially masked by the ptosis).

did not fill from below. The *right lobe* of the thyroid was enlarged to the size of a lemon, displacing the trachea to the left, and felt soft and cystic. No *bruit* was audible over the thyroid. The lungs were clear to clinical examination. The heart was enlarged to the left and downward, the point of maximum intensity being in the 6th intercostal space at the anterior axillary line. The sounds were loud and forceful, and the aortic second sound was louder than the pulmonic second sound. A loud, long, blowing systolic murmur was audible maximally at the apex and was transmitted medially to the left border of the sternum, and upward to the

Neurologic examination. (a) Cranial nerves: The ophthalmoplegia externa has already been noted. Other cranial nerves were normal. The patient spoke with a hoarse voice but oral and laryngoscopic examination revealed no abnormality of the nasal, palatal, or laryngeal muscles or mucosae. The vocal cords appeared entirely normal. (b) Sensory status: normal. (c) Motor power: generalized weakness of mild degree without any paresis or paralysis (other than the oculomotor) was present. This weakness was not affected by an injection of prostigmin administered to rule out any element of myasthenia gravis. Gait was normal, ex-

cept as modified by the weakness. (d) Cerebellar function: normal. (e) Reflexes: The deep reflexes were equal and slightly hyperactive. Abdominal and cremasteric reflexes were normal. Plantar reflexes were normal on the left, but exhibited a Babinski type of response on the right which, however, was not constant.

Laboratory data. Urinalysis, blood counts, erythrocyte-sedimentation rate, blood-sugar, and nonprotein-nitrogen determinations were all entirely normal. The basal metabolic rate was plus 65 percent. Spinal puncture was productive of clear, colorless fluid under normal pressure and with normal dynamics, normal cell count, and protein content (25 mg. percent). The blood and spinal fluid gave negative Kahn reactions. Gastric analysis revealed absence of free hydrochloric acid, even after the injection of histamine. Roentgenograms of the skull revealed no significant abnormality.

Roentgenographic examination of the chest indicated slight cardiac enlargement as gauged by the cardio-thoracic ratio (transverse diameter of heart, 14.7 cm.; transverse diameter of chest 27.7 cm.). However, the contour of the heart and the aorta, and the lung fields were normal.

Clinical diagnoses. 1. Thyrotoxicosis. 2. Cardiac disease: (a) thyrotoxic; (b) enlarged heart; (c) auricular fibrillation; (d) II; (e) C. 3. Cystic adenoma of the right lobe of the thyroid gland. 4. Exophthalmic ophthalmoplegia. 5. Incisional hernia.

Course. In view of the rapid fibrillation and the generalized weakness, digitalis was administered, and effected a decrease in the ventricular rate to 86 beats per minute with a pulse deficit of 6 beats per minute. After digitalization, the basal metabolic rate was plus 32.5 percent. Lugol's solution was then administered daily for a 10-day period, the basal metabolic rate falling to plus 17 percent. Coin-

cident with these decreases in the basal metabolism, the patient reported improvement in strength, decrease of anxiety, and disappearance of palpitation. With a view toward decreasing the strain on the patient's heart, thyroidectomy was considered advisable, despite the duration of symptoms, and an operation was performed under local anesthesia on July 31, 1942. The day following the operation, the patient exhibited collapse, dyspnea, dullness and absent breath sounds over the right lower lobe, and a low-grade fever (37.8°C.). These difficulties were attributed to a postoperative collapse of the right lower lobe, and bronchoscopic aspiration yielded one ounce of thick mucopurulent secretion. Following the aspiration, breath sounds were audible over the right lower lobe, but the patient continued progressively downhill, expiring on August 2, 1942, two days postoperatively.

PATHOLOGIC ANATOMY. *Thyroid.* The thyroid gland removed at operation evidenced enlargement of both lobes, more pronounced on the right side, and weighed 64 grams. The surface of the gland was nodular, and, on sectioning the gland, the nodules were found to vary from 0.5 to 1.5 cm. in diameter. Fresh hemorrhage had occurred into some nodules, while others had a colorless, almost translucent appearance. A small area of calcification was present in one nodule. The fibrous tissue about some of the nodules appeared quite thick.

Microscopic examination of thyroid sections indicated that the nodules, apparently by their expansive growth, had compressed the thyroid tissue at their margins into a thick capsule-like structure (fig. 2). The acini within the nodules varied considerably in size, but papillary proliferation of the epithelium was not evident. However, most of the epithelial cells were of the high columnar type. The colloid immediately next to the lining cells ex-

hibited vacuolization, but was otherwise homogeneous and heavily staining in type. In some nodules foci of degeneration were evident wherein the acini were widely separated by a lightly staining, almost acellular ground substance in which an occasional small nidus of thyroid cells was observed. The colloid material in degener-

The heart was dilated and enlarged, weighing 400 grams. All chambers appeared enlarged, but the left auricle was tremendously dilated. The myocardium was firm, red-brown in color, and showed no scarring. Slight atherosclerosis of the mitral valve and of the aorta was evident, but the coronary arteries were normal. The right ventricular wall measured 4 mm. in thickness, the left measured 13 mm.; the right auricle measured 3 mm., the left 4 mm. The

Fig. 2 (Fagin, Pagel, and Sand). Section through the thyroid gland ($\times 100$) demonstrating colloid retention, variability in size of acini, and compression of thyroid tissue to form a thick pseudocapsule.

ating portions of nodules was more lightly stained than other portions.*

POSTMORTEM EXAMINATION. *Gross anatomy.* The body was that of a middle-aged white male, 65 inches long and weighing 115 pounds. Postmortem rigidity and lividity were evident. Slight exophthalmos was present. Edentia, a recent operative scar of the neck, and a well-healed right rectus scar were noted on external examination. Superficial lymph nodes were not palpable. The body was opened by a Y-shaped incision. There was no increase in free fluid in the peritoneal, pleural, or pericardial cavities, and the serous surfaces were normal. The thymic fat pad was not enlarged.

tricuspid ring was 12 cm. in circumference, the pulmonic ring 7.5 cm., the mitral ring 10 cm., and the aortic ring 8 cm. Microscopic examination of the heart was normal except for the deposition of a moderate amount of yellow granular pigment at the poles of the nuclei. Slight atherosclerosis and intimal fibrosis were seen in sections of the aorta.

The right lung weighed 850 grams, and the left 950 grams. The lower lobes of both lungs (particularly the right) were almost completely consolidated, and the small areas which were not consolidated were extremely congested. The other lobes were crepitant and of the usual gray-red color lightly mottled with black. The bronchi were congested and contained thick

* Professor H. M. Trumbull in his report on the examination of five thyroid glands removed from patients in Brain's series states that these glands exhibited more evidence of colloid retention and less evidence of colloid secretion or transference than goiters characteristic of Graves's disease. The thyroid from our case would also fit into this group.

mucoïd material. On microscopic examination, the alveoli showed varying degrees of polymorphonuclear leucocytic infiltration and minimal amounts of fibrin. Many of the alveoli in addition showed the lightly staining albuminous precipitate from edema fluid. The areas of consolidation varied in size and were mixed with areas of hemorrhage. The bronchioles were filled with purulent material.

Grossly, the other viscera were normal, except for slight enlargement and increase in the consistency of the liver.

hemorrhage into the perivascular spaces. The pituitary gland was normal microscopically.

The right eye was removed from the orbit, and the orbital fat was found to be firm and faintly lobulated. The external ocular muscles were thin and pale. Microscopic examination of sections of the orbital fat revealed no abnormalities. The external ocular muscles showed varying degrees of degeneration. A hyaline or Zenker type of degeneration was the most common type found. In the degenerated areas, the cross-striations and longitudinal striations

Fig. 3 (Fagin, Pagel, and Sand). Section through an external ocular muscle ($\times 100$) from the case reported. The hyaline degeneration and delicate fibrosis are evident. Compare with figure 4.

Microscopically, the liver revealed irregular congestion; other organs, including the thymus, were normal.

The vessels at the base of the brain exhibited a slight degree of arteriosclerosis, and the leptomeninges showed pronounced fibrosis, with hyperemia of the anterior two thirds of the leptomeninges. The Pacchionian granulations extended more laterally than usual. The lateral ventricle and third ventricle were slightly dilated, and the foramen of Monro was widely patent. A few petechial hemorrhages were seen in the anterior portions of the frontal lobes. On the right side there was destruction of a portion of the gyrus hippocampi involving the horn of Ammon. No other focal lesions were found in the cerebral hemispheres. Intensive examination of sections through the brain stem failed to reveal any significant abnormality. The pituitary gland was of normal size. Microscopic examination of the brain revealed only an occasional recent

were no longer visible, and in many places the fibers had degenerated to a round or oval hyaline mass with 3 to 6 nuclei at the margin. These masses took the stain more darkly than did the few normal fibers that remained. Occasional foci of lymphocytic infiltration were scattered through the external ocular muscles, and in the degenerated portions of the muscles there was a delicate and diffuse fibrosis enclosing the many small hyaline masses (figs. 3, 4).

ANATOMIC DIAGNOSES. 1. Nodular colloid goiter. 2. Enlargement and dilatation of the heart. 3. Bronchopneumonia. 4. Exophthalmos, bilateral, slight. 5. Passive congestion of the liver. 6. Degeneration and fibrosis of the external ocular muscles. 7. Emaciation.

DISCUSSION AND COMMENT

The case history presented is of equal interest to the internist and ophthalmologist. The long duration of the symptoms of hyperthyroidism and the variability of the symptoms are unusual. Apparently, the symptoms of hyperthyroidism first developed in 1916, subsided by 1926, re-occurred in 1932, and persisted until death.

patient had taken iodine or other medications at any time previous to his admission to the U. S. Marine Hospital.

The variability in the ocular signs is another unusual feature of this case. It is not certain when the ophthalmoplegia developed, since the patient was not aware that he suffered therefrom. However, it is likely that paralysis of the external ocu-

Fig. 4 (Fagin, Pagel, and Sand). Section through a normal external ocular muscle ($\times 100$).

It is difficult to understand why the patient was not subjected to thyroidectomy earlier in the active phases of his disease.

The variability in the enlargement of the thyroid is another interesting feature in this history. Apparently, the first manifestation of dysfunction was a diffuse swelling of the gland, followed later (1922) by enlargement of the *left* lobe of the thyroid gland. Subsequently the enlargement became symmetrical, but in 1932 with the recurrence of the symptoms of thyrotoxicosis the *right* lobe of the gland became enlarged. The latent periods were apparently spontaneous in development since there was no history that the

lar muscles began to develop in 1940, with the transient diplopia, which was probably secondary to an initial asymmetrical paralysis.

The term "*exophthalmic ophthalmoplegia*" is descriptive of the clinical features of this entity; that is, protrusion of the eyeball in association with paresis or paralysis of the ocular muscles. The ophthalmoplegia is chronic, generally progressive, and is of the *externa* type, involving only the external ocular muscles. The causes of chronic ophthalmoplegia externa have been reviewed recently² and they fall into the following etiologic categories: 1. Cranial trauma. 2. Intracranial

and systemic infections. 3. Increased intracranial pressure. 4. Cerebral circulatory disorders. 5. Poisonings and miscellaneous causes. Exophthalmic ophthalmoplegia is included in the poorly defined miscellaneous group since its cause is unclear.

Brain and Trumbull,³ in a comprehensive review, discuss the clinical and pathologic aspects of exophthalmic ophthalmoplegia from personal observation of 31 cases. Briefly, the exophthalmos and ophthalmoplegia may develop in one or both eyes, the protrusion being more often asymmetrical, either spontaneously during a period averaging about three to four months in a patient with no or minimal constitutional signs of thyrotoxicosis, or within a few days to two years after subtotal thyroidectomy performed on thyrotoxic individuals.

During the development of the oculomotor paralysis, the patient may notice diplopia as a result of asymmetrical involvement. The exophthalmos of exophthalmic ophthalmoplegia is usually of greater degree (averaging 7 mm.) than that encountered in hyperthyroidism (averaging 2.5 mm.) as gauged by exophthalmometric observations. Some edema of the lids generally accompanies the exophthalmos and even papilledema may develop. Unilateral or bilateral ptosis was present in about 25 percent of Brain's patients. The manifestations of thyrotoxicosis (palpitation, nervousness, weight loss, enlargement of the thyroid gland, tremor, tachycardia, elevation of basal metabolic rate, and other features) are usually mild. The prognosis is generally poor. The exophthalmos and ophthalmoplegia attain a maximum in a few months, and then remain stationary or regress only partially, with resultant disfigurement and limitation of ocular function. Treatment by thyroidectomy, irradiation of the thyroid and pituitary

glands, ovarian hormones, or thyroid extract is unsatisfactory in the great majority of instances. For cases exhibiting extreme exophthalmos, Naffziger's orbital decompression operation may be helpful.

The relationship between exophthalmic ophthalmoplegia and the state of function of the thyroid gland is confusing. The evidence *against* any direct causal relationship between thyroid hyperactivity and exophthalmic ophthalmoplegia is impressive, and may be summarized as follows: (a) Exophthalmos alone, or exophthalmos associated with ophthalmoplegia, may develop or increase^{1,3} following thyroidectomy, when the patient clinically is in a *hypothyroid* state, and the basal metabolic rate is normal or subnormal. (b) The symptoms of hyperthyroidism found in association with exophthalmic ophthalmoplegia are usually mild in degree. (c) The administration of thyroid extract or of thyroxine to patients with obesity, myxedema, or goiter very rarely produces exophthalmos.⁴ In those rare cases where it does develop, the general picture is one closely similar to exophthalmic goiter, so that the exophthalmos cannot be attributed directly to the thyroid extract. (d) The exophthalmos of exophthalmic goiter may precede the constitutional symptoms of thyrotoxicosis, and even if the hyperthyroid state is terminated by extirpation of the gland or by spontaneous subsidence, the exophthalmos generally persists and may become even more severe. (e) The age and sex incidence of exophthalmic goiter and of exophthalmic ophthalmoplegia are different.⁵ Exophthalmic goiter affects females more frequently than it does males—in the ratio of 9 to 1; in exophthalmic ophthalmoplegia, this female preponderance does not exist. The average age of patients with exophthalmic goiter is in the middle thirties, that of patients

with exophthalmic ophthalmoplegia is in the late forties. (f) Smelser⁵ reported that the injection of anterior pituitary extract (containing thyrotropic factor) produced exophthalmos regularly in thyroidectomized guinea pigs. Friedgood⁶ also found that exophthalmos was more readily produced by anterior pituitary extracts when the guinea pigs were in a state of thyroid deficiency. Similarly, Marine⁷ found that exophthalmos was more readily produced in rabbits by methyl cyanide after thyroidectomy.

These findings militate rather strongly against ascribing any direct causal relationship to the thyroid in exophthalmic ophthalmoplegia. The problem is complicated by the complexity of the interrelationships between the endocrine glands. It has been shown in experimental animals that exophthalmos can be produced by the injection of anterior pituitary extract^{5,6,7} even in thyroidectomized animals. Whether human exophthalmos is due to an increased secretion of the thyrotropic factor of the anterior pituitary hormone, or to a decreased secretion of active antithyrotropic factor, or perhaps to both, is not clear. Marine⁷ has suggested that exophthalmos (in guinea pigs, at least) may be due to excessive anterior pituitary secretion acting directly on a sympathetic center in the hypothalamus, or acting indirectly through the gonads on that center. However, that theory does not appear tenable in the light of Smelser's finding⁵ that removal of the cervical sympathetic ganglion does not prevent the development of exophthalmos in guinea pigs. Another difficulty is that excessive thyrotropic activity has not been demonstrated in the blood or urine of patients with thyrotoxicosis.⁸

A significant addition to the study of exophthalmos was made by Smelser's observations of the orbital tissues.⁵ He found that in both experimental and hu-

man exophthalmos the orbital tissue was excessive in amount, the retrobulbar connective tissue, the fat, and the external ocular muscles being edematous and infiltrated with wandering cells. The exophthalmos was attributed to the mechanical effect of the increased orbital tissue. We were unable to demonstrate edema of the orbital tissues or of the external ocular muscles in the case reported here.

Brain and Trumbull³ ascribe the exophthalmos to an increase in pressure in the fat-containing cone formed by the globe and the external ocular muscles, the posterior surface of the globe forming the base, the muscles forming the sides, the muscular attachments to the bony orbit forming the apex. The increased pressure presumably results in mechanical restriction of the motion of the eyeball, and interference with venous drainage results in edema of the muscles and orbital tissues. McGregor¹ postulates that cellular infiltration of the orbital tissues then occurs, which, together with the edema, results in an increased volume of orbital contents, with subsequent degeneration of the muscles. That such a hypothesis, although teleologically satisfactory, is not completely adequate is indicated by its failure to explain the ophthalmoplegia in such cases as that reported by McGregor himself, wherein the paralysis preceded the exophthalmos by three months.

A somewhat different explanation is tendered by Galli-Mainini,⁸ based on the probability that there is a tendency toward the development of edema in hyperthyroidism (resulting from increased pulse pressure, subnormal serum-protein levels, capillary dilatation, and increased capillary permeability). These *edematogenic* factors, acting with myasthenia of the oculomotor muscles, result in an increase of volume and pressure in the orbit, and exophthalmos. Degeneration and lymphocytic infiltration of the extra-

ocular muscles presumably causes the ophthalmoplegia.

The treatment of exophthalmic ophthalmoplegia is a difficult clinical problem. It has been stated that thyroidectomy is the measure most definitely contraindicated in Graves's disease with dissociation of thyrotoxicosis and ophthalmopathy,⁹ and the treatment recommended is to lower the basal metabolic rate with iodine to as low as it will go and then add thyroid hormone. Means and co-workers⁹ point out that the metabolic action of the thyroid and the iodine will cancel each other, but it is the diuretic effect of thyroid that is desired in order to reduce orbital swelling. In the patient presented

in this report, the thyroidectomy was considered advisable because of the cardiac factor; however, in retrospect, in view of the good response to the administration of digitalis and iodine, perhaps it would have been wiser to have continued those measures, and, if necessary, to have irradiated the thyroid later.

SUMMARY

1. The clinical history and findings of postmortem examination of a patient with exophthalmic ophthalmoplegia are reported.

2. The syndrome of exophthalmic ophthalmoplegia is briefly reviewed.

DUTIES AND TRAINING OF AN ORTHOPTIC TECHNICIAN

WALTER B. LANCASTER, M.D.

Boston

It is clear that before planning a suitable course of study and training for an orthoptist we must come to some agreement as to the proper functions or duties of an orthoptist. It seems to me that the proper or specific sphere of the orthoptist is the dealing with disturbances of binocular vision and ocular motility and the teaching and training of the patient in the proper use of the two eyes by means of special exercises—"Reëducation of the brain to use the two eyes together," to quote Miss Billingham. It may be a matter of convenience to add other duties to this, her proper field, but for the purposes of fruitful discussion these supernumerary activities should be omitted. I have no quarrel with those who wish their flutist to double in brass and who therefore seek an orthoptist who is a perimetrist, a diagnostician, or even a refractionist or an expert in dealing with reading difficulties or an office nurse. What I am insisting upon is that these are not a part of the proper, or specific, exclusive sphere of the orthoptist.

In her capacity as an orthoptist it seems to be generally agreed that she should act in coöperation with, and under a certain amount of supervision by, an ophthalmologist. It is the proper or specific sphere of the ophthalmologist to make the diagnosis and plan and supervise the treatment. However, he can delegate certain details to assistants; one may measure the refraction, another may measure the motility. Just as the surgeon delegates the details of administering a general anesthetic to a specially trained anesthetist who is given rather a free hand, and as the laboratory technician is given a free hand in carrying out a requested blood test, so when the ophthalmologist

decides that orthoptics is indicated he need not specify what in detail should be done by the orthoptist. If he is wise he will leave that to one who knows much better than he how to deal with the details. If the ophthalmologist makes any bluff of pretending to know, he may be sure the orthoptist will see through it very easily and he will be given a corresponding place in her estimation—she is usually a good diagnostician in that field.

But the ophthalmologist should weigh the data furnished him and plan the treatment, whether by wearing glasses, perhaps with prisms, by orthoptic exercises, by operation (and if so what operation and when), and by postoperative training.

From this it follows that diagnosis is not the function of the orthoptist except in a limited but very important way. This consists in making certain measurements of function or performance.

FUNCTIONS OF THE ORTHOPTIST

The orthoptist makes certain measurements:

(1) Visual acuity of each eye, separately and together, with and without glasses (bears on amblyopia, on alternating, on possibility of progress).

(2) Sometimes measures range of accommodation: Positive by —sph. and the near point of accommodation; negative by +sph.

(3) The deviation, whether phoria or tropia: A, by inspection (cover test and prisms); B, by instruments (amblyoscope, and other apparatus).

(4) Retinal correspondence and projection, normal or anomalous.

(5) Binocular vision analyzed according to the three established grades,

(6) Suppression must be investigated (very important).

(7) After determination of the deviation and fusion status, the amplitudes should be measured.

(8) Psychology: Patient's grade of intelligence, ability to coöperate, to concentrate. Patient's stage of growth (maturity); need of discipline; planning rewards. Mother: intelligence; coöperation; possibility of home treatment.

(9) The case must be analyzed and the problem clearly perceived as it exists at the present stage.

(10) Decide on the line of treatment. Have something definite in mind as the first goal. Work with precision toward the needs of the individual. Avoid haphazard fumbling. Avoid routine ruts. Avoid waste of time on what patient has already learned or what he is at present incapable of doing.

There are refinements of diagnosis important to the orthoptist but having little bearing on the treatment given by the ophthalmologist. For example, it is very important for the orthoptist to evaluate the patient's intelligence and actual capacity for coöperation; can he or, if he can, will he look at an object when told to? Some are not old enough to coöperate sufficiently to do this, some need discipline. Is the patient himself, or is his mother, capable of carrying out homework? If this is not diagnosed correctly much time and futile effort may be expended.

There are refinements of diagnosis important to the ophthalmologist but having little bearing on the treatment given by the orthoptist.

The ophthalmologist may wish to know the deviations as measured in the nine cardinal positions of gaze (often spoken of as six), though these rarely have any bearing on the work of the orthoptist who is satisfied to know the deviation in the

primary position for distance and near and occasionally looking to the right, to the left, up, and down. I feel that much time is expended on irrelevant, unnecessary (though not uninteresting) measurements when the orthoptist might be much better employed otherwise.

WHAT MAY THE ORTHOPTIST EXPECT OF THE OPHTHALMOLOGIST?

The ophthalmologist should report to the orthoptist:

(1) Findings with the ophthalmoscope, especially those bearing on amblyopia.

(2) Visual acuity, with and without correction.

(3) Refraction.

(4) Deviations, nature and etiology of deviations, if known. This is outside but close to the field of the orthoptist, who is not to be expected to be competent to investigate this problem but who may profit greatly from information which will help in making the prognosis, help her to answer the difficult question: How long will it take to cure this patient? (An important theme for research: Why do some get well in a few weeks while others, who appear similar at the start, take months?)

(5) History of treatment: Occlusion, glasses, orthoptics, operations, with details. Important information best furnished by the ophthalmologist rather than by the orthoptist by questioning the patient or mother.

(6) Conference or consultation, at least by telephone, at different stages of progress.

(7) Finally, the ophthalmologist should have sound and correct conceptions of the nature of the orthoptist's work. There are still many ophthalmologists who cling to the conception that disturbances of motility are due fundamentally to "muscle trouble"—some mus-

cle is weak or some muscle too strong. Inevitably they think of the orthoptist's work as trying to strengthen some weak muscle. The teacher of piano playing requires hours of practice playing scales and five-finger exercises, not to strengthen the muscles of the fingers and arms. The best player is not the one with the strongest muscles but the one who has the skill to use them. Proper use of the eyes is something that can be taught.*

WHAT SHOULD BE THE RELATIONS BETWEEN OPHTHALMOLOGIST AND ORTHOPTIST?

(1) The ophthalmologist is in charge and entitled to dictate.

(2) Ideally, conference and consultation between the two should prevail, since each can contribute to solving the problems, each knows things the other does not know.

(3) When the ophthalmologist assumes the role of superiority the best way for the orthoptist is to assume the role of humility (and pity) but proceed, by deeds and by achievement impossible to the ophthalmologist, to show him the better way. Do not start by antagonizing him, leave him a chance to save his face.

(4) The ophthalmologist who would get the most out of the orthoptist should give her a free hand, offering suggestions in a friendly way, not in a dictatorial way.

(5) If there are differences of opinion, an attempt should be made to solve them by intelligence and discussion. Nothing is finally settled until it is correctly settled.

Having outlined the duties of the orthoptist, one is now prepared to take up the question of training or preparation of the orthoptist. As in the training of the

ophthalmologist, it will be found that since many, very many things will be useful the chief problem is the relative importance or value of different subjects. Where should the emphasis be placed? Time devoted to this must be taken from that.

First of all, it is to be hoped that some consideration will be given to aptitude. Is the person of a type likely to be successful as an orthoptist? The mere fact that she is fond of children is not enough, this might do for a nursery maid. It requires a fairly high degree of mental equipment plus the training—preorthoptic and orthoptic—to make a good orthoptist. Mediocre intelligence will not shine in orthoptics.

TRAINING OF THE ORTHOPTIST

WHAT IS THE BEST PREPARATORY (PRE-ORTHOPTIC) COURSE?

Training as a nurse, secretary, or laboratory technician does not offer the best basis for orthoptics. But the normal-school teacher, or one who has majored in psychology at college, or one experienced in kindergarten work has an advantage over even the graduate in optometry or in medicine.

ESSENTIALS OF A COURSE IN ORTHOPTICS

Anatomy and Embryology. One can be a good orthoptist with only a smattering of anatomy of the ocular muscles and their blood and nerve supply—quite different from the ophthalmic surgeon. The orthoptist needs to know enough about the muscles to understand what the surgeon is trying to accomplish by his operations and to be able to give him good advice regarding operations. Thus she needs to know the different types of operation. She soon learns who among the surgeons get good results.

Physiology is very important, since orthoptics deals with functions and with

* See paper on "The role of exercises in ophthalmology." Trans. Amer. Acad. Ophth. and Otol., 1943.

reflexes in particular. A knowledge of the physiology of muscle, of nerve is important; also of the reflexes, conditioned reflexes. The secretions and the circulation are relatively unimportant. In physiology the instruction should be highly selective and specialized to fit the need of the orthoptist and give her a sound background so that she can understand the working of the visual organs, their possibilities, and their limitations. A smattering of *optics* (less even than that of the average ophthalmologist) is sufficient; also a smattering of lenses and prisms.

Physiologic optics. Training in this subject should include a smattering of *errors of refraction*. The student of orthoptics should know something of *accommodation*, especially the near reflex, which involves the accommodation, the pupil, and convergence. The study of *visual acuity* should comprise foveal and peripheral vision; the influence of age (infancy) on vision. A knowledge of *amblyopia*, *scotoma*, *suppression of small or large area of the retina* is recommended. *Binocular vision*, its three grades, should be studied: the states of development in infancy and childhood; corresponding and disparate points; fusion, motor and sensory.

The field of *ocular movements* should cover: *monocular*—fixation, reciprocal innervation; *binocular*—diplopia, fusion reflex, diplopiaphobia. Ocular muscles never work singly; effect of deficiency of a single muscle. All of the ocular muscles very strong, 100 times as strong as needed to move the eye. Innervation to ocular muscles always equal to both eyes. The two eyes act as a single organ, the binocular.

Psychology is very important, especially applied psychology, covering growth and maturity; habit formation and control; learning (a large chapter); attention—capacity for concentration—influ-

ence of age; parents and home life; discipline—fears, rewards; application of teaching methods to orthoptics, especially elementary teaching—for example, methods of teaching spelling, reading, and so on; how to win the patient's confidence and coöperation—for example, by explaining the nature of the defects and the way the training achieves results and some of its limitations, and like factors.

Parents and intelligent patients are eager for such instruction and have a right to expect it. If the doctor does not give it (and he may not have the time) he should welcome the aid of the orthoptist in this important but much-neglected work. As a teacher she should be well fitted to teach the parents. If people are not taught by someone who knows, how are they to avoid the specious claims of charlatans or even of honest but ignorant practitioners? Moreover, patients crave understanding of their troubles. They wish to know why they are afflicted, what the causes are, what the remedies are, what the outlook will be. It is not easy to answer these questions when the questioner is as ignorant as most of them are. Hence some doctors fall back on easy evasions or sweeping generalities or old-time popular pathology, "The patient has a lazy eye or lazy muscle." Then if the orthoptist makes the matter clearer in plain language the patient or the mother thinks the orthoptist knows more than the ophthalmologist. Perhaps they are right.

PRACTICE

The student should become familiar with: (1) the technique of the use of the instruments; (2) analyzing the visual problems; (3) planning treatment for specific problems; (4) discipline; (5) handling parents; (6) home work. It is not enough to tell the patient *what* to do—for example, bar-reading, which is often very difficult to accomplish correctly.

The influence of age is well illustrated by the progress of a child with convergence. He makes fairly good progress until he gets down to 10 degrees. There he often sticks discouragingly. He suppresses in spite of you, but when he learns to read he can be taught not to suppress and makes rapid progress.

(7) Reporting to doctors. The orthoptist has duties to satisfy the doctor, the parents, the patient.

The doctor wants to know if this case is one orthoptics will cure. He should (and would if he were wise) want the opinion of the orthoptist as to various matters of treatment including when to operate. He wants the patients to have confidence in him, hence the orthoptist must be very wary in her frequent conversations with the parents and the patients, striving to build up their confidence in the doctor, ready with explanations as to why operation is done or not done, "Trust the doctor, it is his job to decide such questions." "I have seen some splendid results with his cases." "He has had great experience in such cases." Unfortunately, patients are often keen enough to perceive that the doctor knows much less about his particular case than the orthoptist, who, of course, sees him 10 times to the doctor's one. However, some doctors prefer an orthoptist who does not know so much.

The orthoptist's duties to the parents cover:

- (1) Explanation of the problem and of the treatment. The parents have more frequent contact with the orthoptist, become less afraid to ask her questions, and are very grateful for such information. To refuse it could have a bad effect on the relations between parent and orthoptist.
- (2) Instruction in home coöperation.
- (3) Satisfactory discipline.

The orthoptist's duties to the patient call for (1) understanding and (2) more

understanding, (3) complete understanding. Factors are A, his age; B, his intelligence; C, his environment (note the marked change in attitude that comes soon after the child begins to go to school); how to manage motivation (rewards, praise, commendation, and the like as well as punishments); D, anatomic situation.

SUMMARY

Ophthalmologists, in planning the proper course of study for an orthoptist, have over-emphasized certain parts of such subjects as anatomy, optics, some branches of physiologic optics; they have under-emphasized some aspects of physiologic optics, and especially of psychology, the science and art of teaching, the behavior of children, the fundamentals of learning, of acquiring new habits and eliminating old ones. It is easy to see why this should have happened since the doctors naturally stress the subjects they know something about and the subjects they know from experience are important in their own work. Knowing little about orthoptics they do not know what to emphasize.

Far be it from me to belittle the importance of the basic subjects, I have been pleading for them for years. It is the *relative* importance that I am advocating. All education involves frequent choices. I can take this only if I omit that. Hence the crucial decisions are: What can or must be omitted? I submit that in the training of orthoptists the failures have been not in the basic ophthalmic subjects but in the basic subjects of psychology, the art of teaching, the laws of learning, the ways of habit formation of conditioned reflexes.

Another thought is that perhaps orthoptics in this country has become inbred and needs crossing with new and different ideas to become most fertile.

520 Commonwealth Avenue.

TREATMENT OF ASTHENOPIA—NONPATHOLOGIC AND NONREFRACTIVE IN ORIGIN

RALPH H. PINO, M.D., AND GRETA L. HULTIN, M.A.

Detroit

A certain percentage of patients who consult ophthalmologists because of asthenopic symptoms are not relieved by glasses or other usual methods. Many of these give evidence of nothing that falls within the sphere of recognized diagnosis. A study of 125 of these difficult and dissatisfied individuals in our office leads us to believe that they manifest asthenopia from disturbed muscular coördination and/or fusional amplitude too small for classification, or spasm from muscles long held in restricted positions, passive congestion, and failure of smooth interaction of muscle and tendon, in relationship to adjacent tissues.

In our experience this group of 125 cases falls in a classification quite independent of the usual disturbances of coördination such as definite phorias and tropias, and they are seemingly all independent of refractive disturbance or intrinsic or surrounding pathologic factors. We believe there develops in many people a condition that disturbs the smooth, normal mechanical relationship of muscle and tendon and their coverings of tendon sheathes, Tenon's capsule, and the like, which produces various asthenopic symptoms. As muscles of the body generally become less pliable and interact with discomfort when not normally exercised, so the ocular muscles can, by assuming rather restricted action during long hours, become relatively fixed so that the movements less frequently required produce discomfort, as, for example, discomfort of the back muscles after bending over an operating table for prolonged periods.

Patients who do close work for long continuous periods sometimes are found to have in their eye muscles a condition

analogous to the aforementioned backache. These muscles have been held in a converged, or other position so long that the eyes do not relax for an uncomfortably long period; or else they become comfortably fixed in these long-held positions and produce discomfort on being moved to less usual positions. Symptoms of our patients varied from constant or frequent headaches in 53 instances, to tearing, blurring, twitching, and general visual discomfort in the remaining 55 complete cases studied.

An occupational survey of the 44 men and 64 women patients reveals that 45 were confined to offices, 27 were students, and, of the remainder, 22 were housewives, 9 were professional people, 3 were salesmen, and 3 were employed in factories. The age range was from 12 to 54 years.

Uncorrected refractive errors and other visual irregularities, sinus disease, and like affections, which may be factors in asthenopia were ruled out insofar as it was possible to do so. All but eight patients attained visual acuity of 20/20 in each eye. The exceptions had acuity of at least 20/50 in each eye.

A specific diagnosis of the causes of the asthenopia found in this group of cases seems to us exceedingly difficult. Some of the patients had difficulty in abducting or adducting their eyes, hence they might be characterized as having "poor ductions," or a disproportionate relationship between the prism diopters of convergence or divergence, low "amplitude of divergence and convergence," or "insufficient amplitude of fusion areas." There is a little difficulty here in that too little agreement has been found as to defini-

tions for these terms. Nor is the relationship which should exist between factors such as abduction and adduction agreed upon. It is generally stated, however, that a "reasonable amplitude of convergence" is necessary to comfortable vision. We assume that some of our patients suffer from a lack of "reasonable amplitude of convergence."

Other diagnostic phrases that have also been suggested are "minimal binocular coördination," "disturbed binocular coördination," and "insufficient fusion span." But here again we find ourselves at a loss for lack of standards for measuring purposes.

We reach our decision as to the needs of the patient without benefit of special vocabulary. Our "technique" is most easily illustrated by a few examples.

A patient seated before the Synoptophore cannot hold two unlike figures superimposed at or near his phoria point. When he attempts to use his eyes simultaneously his fixation is poor. Asked to fuse identical objects he suppresses either alternately or monocularly. If "print jumps and blurs before the eyes after a short period of reading" and if headache develops in spite of refractive correction and other visual procedure, we try a series of exercises. Some persons suppress constantly when a load is put on, thus eliminating the necessity of coördination.

Another patient has no difficulty holding his eyes steady, but although he can abduct and adduct for what seems a reasonable degree he does so only with great effort and fatigue. His eyestrain if not otherwise relieved is frequently overcome with carefully administered exercises. Take such a patient's muscle balance with the phoropter and he may seem normal in the usual hurried examination, but hold him to it and he may manifest considerable muscular difficulty.

A third patient has difficulty adjusting

accommodation and convergence quickly from one distance to another. He sees acutely after going through a period of conscious adjustment during which objects are blurred and occasionally double. A few exercises may make this adjustment more normal and comfortable.

As may be expected, a fair proportion of the cases classify themselves rather readily as convergence-insufficiency or -excess, or divergence-insufficiency or -excess problems. However, original phorias were normal in 80 instances, 15 patients were exophoric, and 13 were esophoric. No trophias were included. Original "ductions" findings were poor in 79 instances, fair in 26 instances, and 4 patients had excellent ductions before beginning exercises. All but one patient had stereopsis, although with 13 patients this was of a very low grade.

At the conclusion of remedial exercises, phorias were found to be essentially unchanged. Improvement in "ductions" varied from 5 to 25 prism diopters. However, the conclusion that this improvement brought comfort does not, except in a few cases, seem warranted.

It is generally acknowledged that the ability to compensate for or to ignore weaknesses varies markedly in persons, and it is not far-fetched to assume that a systematic exercising of the various ocular muscles may result in a general improvement in the mobility of the eye muscles to the extent that the specific difficulty, if not incidentally corrected, may be more easily overcome.

We subjected each of these patients to a series of orthoptic exercises designed to correct the particular types of weaknesses toward which each showed a tendency and/or in general just to limber up the muscles and improve circulation. Many of the patients received base-in and base-out exercises sometimes combined with accommodation, alternation, or rotational

exercises. Some were given exercises especially designed to stimulate fusion by the foveal area; others received binocular peripheral stimulation. Exercises were given at both near and far points. Most of the work was done with a Rotoscope supplemented with the Synoptophore, the Tele-trainer and the Junior Metronoscope with prism attachment. The exercise period varied from 15 to 25 minutes, depending upon the type of exercise given. A trained technician remained constantly with each patient during an exercise. We believe constant, intelligent direction to be essential to effective orthoptics, particularly when it is desired to give a minimum number of exercises.

The number of exercises given to the patients varied from 3 to 21. However, the optimum number seemed to be 6 exercises, the first 4 being given bi-weekly, the last 2 at intervals of a week.

Home exercises were prescribed for two thirds of the patients. In seven instances these were the conventional stereoscope exercises. The other two exercises used were the well-known finger-to-nose convergence exercises and an equally simple divergence device familiar to our patients as the "thumb exercise."

Since this "thumb exercise" is flexible, simple to teach, and amazingly effective as a "relaxing" device, a brief description of it seems warranted. To perform the exercise, hold up the right thumb, 13 inches in front with good illumination at the back. Looking through to infinity will produce physiologic diplopia and two thumbs are seen out of focus. Now arrange the left thumb beside, parallel, and level 65 mm. from the first. Four thumbs will be seen with a little practice; one can fuse the middle two thumbs and by asymmetric stereopsis project a third thumb. To exercise the lateral recti, gradually separate the two thumbs until the middle thumb is distorted against effort. The il-

lusion will be aided and fixation stimulated if a spot is marked on each thumb nail with India ink about 2 mm. lateral to the midline. This spot will then appear to stand out in relief an inch closer than the thumb nail. Patients to whom this exercise is prescribed usually perform it several times a day for periods not exceeding one minute.

Relief from asthenopia was complete and thus far permanent (the program was begun two years ago) as concerns 108 of this group of patients. In several instances comfort followed many years of headaches and visual fatigue, in spite of glasses and other usual therapeutic procedures.

Of the 125 cases included in the study, 17 patients did not respond satisfactorily to remedial exercises. Various factors such as poor coöperation, absence from treatments, and illness were present in these instances and may have contributed to the lack of success.

As massage may give much relief in general to congested, stiff, and painful muscles anywhere in the body, so the orthoptic department of any ophthalmologist's practice can serve in addition a most helpful purpose over and above the more definite procedures for which such exercises are more commonly used.

SUMMARY

A study was made of 125 cases of asthenopia in patients who were not relieved by glasses or other means. This group did not consist of those with definite muscular difficulties, such as definite convergence insufficiency and the like, but rather those who, for no apparent reason, had difficulty in doing sustained close work. The ages ranged from 12 to 54 years, with a mean age of 28. There were 44 men and 64 women in the completed cases; 27 were students, and of the remaining 37, 22 were housewives, 9 pro-

fessional people, 3 were salesmen, and 3 were employed in factories.

The vision in all but eight patients was 20/20 O.U., the others having at least 20/50 O.U. Orthoptic exercises varying from 3 to 21 sessions were given with the Synoptophore or other orthoptic instruments. Seventeen of the 125 failed to respond satisfactorily to remedial exercises. Poor coöperation and failure to take the optimum number of exercises, which was

found to be six, may have been contributing factors.

It is thought that as massage may give much relief in general to congested, stiff, painful muscles anywhere in the body, so the orthoptic department in any ophthalmologist's office can serve in addition a most helpful purpose over and above the more definite procedures for which such exercises are more commonly used.

NOTES, CASES, INSTRUMENTS

CAVERNOUS-SINUS THROMBOSIS WITH RECOVERY

REPORT OF A CASE

A. C. GOETZMAN, MAJOR (MC), A.U.S.
AND R. FRIEDMAN, LIEUT. (MC), A.U.S.
Camp Butner, North Carolina

A soldier, 20 years old, was admitted to the Station Hospital on April 30, 1943, complaining of swelling of the nose and face, chills, and fever. Four days previously he had first noticed a small, red, painful swelling on the tip of his nose. This progressively increased to involve the upper half of the face at the time of hospitalization. Two days prior to admission he had had a shaking chill of 30 minutes' duration. Except for a mild sunburn no history of previous trauma or infection could be obtained.

Initial examination showed an acutely ill young, white, male complaining of painful swelling of the nose and face, the upper half of which was swollen, red, and tender. Although there was edema of the lids the eyes could be opened voluntarily, and there was no proptosis. The conjunctiva of the globes was moderately injected but not edematous. The pupils were round, equal, and reacted to light and accommodation. The eyegrounds appeared to be normal. Breathing was par-

tially obstructed by the swollen nostrils, from which exuded a small amount of serous discharge. The neck was not rigid. Petechiae and rash were both absent. Physical examination was otherwise negative. His temperature was 104.2°F., the pulse rate 122, and respirations 34 per minute. The white-blood-cell count was 13,200, with 92 percent polymorphonuclears.

A diagnosis of cellulitis of the face originating from a lesion on the nose was made.

A blood culture was taken on the first day and 5 gm. of sodium sulfadiazine in distilled water administered intravenously. Sulfadiazine—2 gm. every four hours—was given orally. Continuous wet boric acid dressings were applied locally.

The next day chemosis appeared and the edema of the lids became more marked. By the fourth day it was apparent that a bilateral cavernous-sinus thrombosis had developed. At this time the lids were so swollen that they could no longer be opened, and the ocular conjunctiva projected between the lids. Both eyes were proptosed and immobile. The supraorbital and palpebral vessels were markedly dilated. Fundus examination revealed engorged and tortuous veins. The optic discs were still well defined, with moderately

deep physiologic cupping. There were no retinal hemorrhages nor edema. Thick yellow pus was draining from three openings on the nose. The blood culture taken on the day of admission was reported positive for *Staphylococcus aureus haemolyticus* on May 3d, and sulfathiazole—2 gm. every six hours—was substituted for sulfadiazine. The patient became irrational and his temperature remained elevated. A white-blood-cell count of 20,000 was recorded at this time.

On the sixth day the patient was given a whole-blood transfusion (500 c.c. citrated). On the following day the swelling and induration has spread to the right mandible. Much of the ocular conjunctiva projected between the lids; drying was prevented by the use of a bland ointment and constant wet boric-acid dressings. On the same day he received 60,000 units of staphylococcus antitoxin (Lederle) intravenously and 40,000 on the following day. Twenty-four hours after the administration of the first of these treatments the patient's mental state improved and the temperature dropped to 101.4°F. From this day improvement was steady, with rapid recession of the facial edema. On the sixteenth day the dosage of sulfathiazole was reduced to 1 gm. every six hours and was discontinued three days later, after four days had passed in which the temperature was normal. The results of examination were now negative except for a residual distention of the palpebral vessels, which continued to improve, but was still present at the time of discharge on June 26, 1943. Vision was 20/20 in each eye, and the results of a fundus examination negative. Except for an occasional headache, the patient had no symptoms during convalescence.

SUMMARY

A case has been presented of a 20-year-old soldier who developed cavernous-

sinus thrombosis secondary to a pustule on the nose. Blood culture was positive for *Staphylococcus aureus haemolyticus*. During the first three days of hospitalization he received 5 gm. of sodium sulfadiazine intravenously and 36 gm. of sulfadiazine orally. After receiving the report on the blood culture sulfathiazole was substituted for sulfadiazine, and of this he received 116 gm. over a 16-day period.

The first signs of improvement appeared on the eighth day, 24 hours after an intravenous injection of 60,000 units of staphylococcus antitoxin. This was repeated with 40,000 units on the following day. The patient's condition, which had been critical up to this point, rapidly improved, so that at the time of discharge, on June 26, 1943, he showed only a mild residual distention of the palpebral vessels.

In view of the rapid improvement following the use of antitoxin one is tempted to attribute much of the good results to this therapy. Whether or not a favorable outcome would have been obtained if sulfonamides had not been used in conjunction with the antitoxin is uncertain. In such a critical condition one is prone to run the gamut of treatment and in so doing lose the ability to assess the value, individually, of the medications used.

Station Hospital.

BINASAL HEMIANOPIA

IRWIN E. GAYNON

LT. (MC), A.U.S.

Binasal hemianopia is that condition in which the nasal half of each field has no light perception. This type of field is rare, and is seldom of perfect bilateral division.

FREQUENCY

Von Graefe (1858) described one case which he considered to be due to the

bizarre effects of a bilateral lesion of the occipital lobes. Mooren (1867) recorded one case as the result of hysteria. Daae (1869) reported six cases associated with optic atrophy in the same family which was considered to be an abiotrophy. Knapp in 1873 reported one case which he attributed to pressure of the sclerosed carotids on the optic chiasm, in a case of generalized arteriosclerosis. Herschel (1883) reported one case with bilateral optic atrophy. He believed the patient to have had symmetrical hemorrhages in the occipital lobes. Henschen's case (1890) revealed a gumma surrounding the optic chiasma. In the same year Von Graefe wrote of a case caused by a gumma extending from the base of the brain to the optic foramen. Lang and Beavor (1894) cited a case due to tabes dorsalis in which the nasal defect was attributed to selective optic atrophy. Rakowicz (1895) reported one case with optic atrophy of unknown origin. Bull also reported a case in that year with optic atrophy. Fridenburg (1896) cites an instance in which binasal hemianopia occurred 18 months after a man had been struck on his head. Burnett (1900) reported a case following a fall on the head. Eskridge, Schmidt and Wegner, and Veasey (1897) each reported a case with papilledema due to brain tumor. Coppez (1911) considered his case to be due to thrombi in both occipital lobes following cardio-renal disease. Cushing and Walker (1912) cited a case in Leber's disease. They also found that 17 out of 300 patients with intracranial neoplasm showed hemianopic defects with a tendency toward binasal blindness and all followed a far-advanced consecutive optic atrophy. They also presented one case due to pressure of sclerosed carotids. Heed and Price (1914) described one case due to tabes dorsalis. Hartman (1933) found his case to be due to post-hemorrhagic blindness. Banduin (1934)

reported a case with acoustic neuroma of the cerebellopontine angle. Löwenstein (1935) reported a case with optic-nerve atrophy due to pressure of atheroma of the carotid arteries. Duncan (1936) presented two cases of intracranial tumor with optic atrophy (1) right cerebral hemisphere; (2) left frontal lobe; and one case of congenital lues with binasal hemianopia. Rouquier and Gaults's (1937) case was due to a probable arachnoiditis. Torkildsen's case (1938) was caused by a meningioma of the posterior cranial fossa.

ETIOLOGY

From the data presented in the literature, the following etiologic factors have been collected: (1) The most common cause is distension of the third ventricle by intracranial tumor with resultant pressure upon the optic nerve by the circle of Willis. (2) The optic atrophy itself may be a cause. This may be considered under: (a) tabes dorsalis, and quoting from Fuchs "We must assume that the tabetic degeneration, as a rule seated in the optic nerve may locate itself farther back in the chiasma;" (b) idiopathy; (c) Leber's disease; (d) trauma; (3) syphilis; (4) pressure on the lateral fibers of the chiasma by thickened arteriosclerotic internal carotids; (5) hysteria.

It might be noted that the lesions, ascribed to a central origin, were not studied *post mortem*.

CASE REPORT

R. F., a white boy, aged 13 years was first seen at the Children's Hospital (Chicago) on May 9, 1934, suffering from an acute right mastoiditis and a *Streptococcus viridans* septicemia. Ocular examination at this time was considered negative. A simple mastoidectomy was performed on May 19, 1934; the patient developed a lateral-sinus thrombosis on May 23, 1934.

The jugular vein was ligated and the clot removed. The postoperative course was extremely septic, with recovery two months from onset. A bilateral optic atrophy was discovered on June 18, 1935, while the patient was being treated in the endocrine clinic for obesity and a probable Lawrence-Moon-Biedl syndrome. X-ray report of skull on July 23, 1935, showed no evidence of brain disease but a slightly larger than normal sella. On August 7, 1935, a divergent

Fig. 1 (Gaynon). Visual field, showing the field for red cross-hatched.

strabismus was first noticed. All laboratory tests on spinal fluid and blood reacted negatively. Vision had been stationary for the past four years: O.D., 20/100; O.S., 20/200, with correction.

The father had died of nephritis at the age of 42 years; the mother had syphilis.

The patient was again examined on September 24, 1941, when the present defect was discovered. Physical examination revealed an intelligent, fairly obese youth of 13 years, whose only complaint was poor vision. Positive findings were mastoid scar, scar over right jugular vein, and tonsillectomy.

Ocular examination. Vision O.D., was 16/200, corrected to 20/200; O.S., 20/70+1, unimproved by correction.

Refraction. Vision O.D. with a +0.50D. sph. \approx 1.00D. cyl. ax. 90° was 20/100; O.S. with a +1.00D. sph. \approx 0.75D. cyl. ax. 90° was 20/70.

Both lids were normal. The conjunctiva was slightly injected, the anterior

chamber of normal depth. The irides were blue, the pupils equal, reacting to light and accommodation and consensually. The optic discs were round, not elevated, pale white in color; their margins fairly distinct; the cribriform markings were not seen. The retinal vessels appeared to be normal. The macula seemed to be elevated. Tension (Schiotz) was O.D. 19 mm. Hg; O.S. 19 mm. Hg.

Blood tests showed: Wassermann reaction, negative; red blood cells, 5,440,000; white blood cells, 6,400; hemoglobin, 13.2 mg. Polymorphonuclear cells, 40; eosinophiles, 3; lymphocytes, 49; monocytes, 8.

On October 6, 1941, the spinal fluid was clear, the pressure 200 mm.; the cell count, negative; Pandy test, 0; protein, 13.6 mg.; the Wassermann reaction, negative.

GLUCOSE TOLERANCE TEST 100 mg. glucose given.

<i>Fasting</i>	<i>Blood</i>	<i>Urine</i>
	108	0
0.5 hr.	145	trace
1 hr.	135	0
2 hr.	139	0
3 hr.	135	0

Fig. 2

The X-ray report, stated, as of October 4, 1941: "The stereoscopic X-ray examination of the skull of R. F. shows the sella to be shallow, but the clinoids and its floor are smooth. No abnormal calcifications are seen. The cranial bones and brain areas appear negative.

Ventriculogram reveals an atrophy at the chiasma. Hence, the lesion is due to a probable old healed arachnoiditis."

Visual fields are seen in figures 1 and 2.

SUMMARY

A brief review of the literature is given. An additional case is presented, due to a probable arachnoiditis at the chiasma.

ANTERIOR-CHAMBER IRRIGATION WITH SULFADIAZINE

JOSEPH LAVAL, M.D.
New York

The publication of the successful use of sulfanilamide in the anterior segment of the globe by Igersheimer (this Journal, 1943, v. 26, p. 1045) prompted me to report the following case.

Mrs. R. S., aged 60 years, a housewife, was admitted to the Mt. Sinai Hospital on September 10, 1943, for a cataract extraction following a preliminary iridectomy that had been performed in July. She was extremely myopic and mildly diabetic.

On the operating table an unusual complication arose. The episcleral-limbal suture which I use had been put in place, and the Graefe section had been performed, when suddenly the patient vomited. Before the speculum could be removed a good deal of the vomitus entered the cul-de-sac of the eye undergoing operation. The suture was drawn snugly and the lids were closed until the patient had freed herself of the gastric contents. Then the field was again prepared

sterile and the eyelids opened. The vomited material was flushed from the cul-de-sac with saline solution.

It is considered that the gastric contents are sterile in the absence of achlorhydria but I was fearful of a possible infection even though I had good reason to know that the patient had a normal gastric acidity. Accordingly, a vial of 25-percent sodium sulfadiazine for intravenous use was opened and diluted with physiologic saline to 10-percent strength. A small 2-c.c. hypodermic syringe was filled with the 10-percent sodium sulfadiazine and a hypodermic needle was attached. The needle was inserted into the anterior chamber and the latter was irrigated. The irrigation was repeated twice and then the cul-de-sac was flushed thoroughly with more of the 10-percent sodium sulfadiazine. Following this the cataract extraction was performed without any further complications. The patient was given 15 grains of sulfadiazine by mouth five times daily for the first two postoperative days. Healing and convalescence were entirely uneventful. There was no undue reaction at any time.

Apparently the anterior segment of the globe can well tolerate 10-percent sodium sulfadiazine, and irrigation with this chemical is nonirritating. Whether it prevented an infection in this case is questionable, but the point is that the use of a 10-percent solution of sodium sulfadiazine is safe and entirely innocuous.

136 East Sixty-fourth Street.

EYES FROM AUTOPSIES*

SAMUEL GARTNER, M.D.,
VIRGINIA LUBKIN, M.D.
New York

We have been fortunate in obtaining permission for a great many autopsies

*From the ophthalmologic service of Montefiore Hospital.

which enabled us to remove the eyes. Most of them are removed through the conventional method of placing a speculum between the lids and enucleating the globe. If the autopsy includes the

Fig. 1 (Gartner and Lubkin). Top view of base of skull. O, roof of orbit, which is removed.

brain, we have found it preferable to remove the eyes by the transcranial route, following the method Lambert¹ used. Figure 1 shows the roof of the orbit that is chiseled off, and through it the eye and the orbital contents are removed as one mass. The entire block of tissue is fixed and sectioned. Large slides are made that show the eye with a long section of optic nerve, the extraocular muscles *in situ*, and orbital vessels and nerves in their normal relationship, as in figure 2.

Great care must be taken to make the bodies presentable for burial, so glass eyes which match the original ones are placed in the sockets. Occasional embar-

rassment has been caused when the glass eye slipped out of position.

The following technique was developed to prevent such accidents. After enucleation, a wad of cotton, soaked in formalin, is inserted in the orbit to occupy the space of the globe. This hardens the tissues and forms a good support for the prosthesis. The glass eye is inserted and sutured into position so that it cannot move. The lids are closed, and then a large piece of cotton, saturated with formalin, is applied against the closed lids for a few minutes. The lids become quite rigid, so that they stay closed, and can be opened only to a small extent. A concealed intermarginal suture is occasionally used as an additional precaution.

In one method of attaching the sutures to the glass eye, holes were bored near the nasal and temporal ends with a dental drill. Once they were so prepared, they were satisfactory. However, we broke several eyes while drilling, and found the process tedious.

The method we now use is to apply the middle of a double-arm suture to the nasal and another to the temporal ends of the glass eye and fasten them in place

Fig. 2 (Gartner and Lubkin). Section of eye and orbital contents.

with Canada balsam. There are other adhesive substances which would do as well, provided they were not soluble in water and not affected by formalin.

A large curved needle is threaded on each end of the suture and carried through the tissues at the inner and outer canthus and tied inside the lids. This holds the eye securely and makes a very satisfactory appearance.

Fig. 3 (Gartner and Lubkin). Glass eyes prepared for autopsies. A, suture holes drilled in sides of eyes. B, sutures fastened to eye with Canada balsam.

REFRACTION CLINIC*

DISCUSSION BY DR. ALBERT E. SLOANE†
Boston

A white woman, 55 years of age, became aware of poor vision in the right eye five months ago. She was told that she had retinal hemorrhages. Yesterday she was seen by another doctor who reported that both eyes show no evidence of pathologic change and advised that her refraction be tested. The patient complained primarily of ocular discomfort and blurred vision, especially when reading, following the onset of the "hemorrhages." Her present glasses are one year old and check to within 0.25D. of the findings as follows: She was wearing, right eye +4.25D. sph. \oslash - .50D. cyl. ax. 90°; left eye +4.50D. sph. add +2.25D. sph.

EXAMINATION

Examination revealed: vision O.D. 20/200; with a +4.50D. sph. \oslash - .50D. cyl. ax. 90° it was 20/50 "slow" (patient notes metamorphopsia). O.S. 20/200;

* From the House Officers' Teaching Clinic, Massachusetts Eye and Ear Infirmary.

† Director of Department of Refraction.

with a +4.50D. sph. it was 20/20, add +2.50D. sph. for reading Well's no. 1. Pinhole disc over the right eye eliminated metamorphopsia but did not improve vision above 20/50.

Induced phoria. Vertical orthophoria. Distance 3^Δ esophoria; near 2^Δ exophoria. O.D. was the dominant eye.

During the examination this feature was noted: The vision was much better subjectively when the right eye was occluded, but immediately became uncomfortable and less clear when both eyes were open. Similarly, with the near glass, the patient had no difficulty reading Well's no. 1 type (fine Bible print), whereas with both eyes open the same type was barely legible and not comfortably so.

DISCUSSION

The symptoms usually can be explained in two ways. First, a problem in refraction, or, secondly, a problem in binocularity. In the first instance refraction can immediately be eliminated as the cause of her symptoms since the findings do not essentially differ from the glasses worn. The problem of binocularity may be fur-

ther subdivided as (1) a disturbing heterophoria; (2) aniseikonia. Examination revealed 3D. of esophoria for distance, 2D. of exophoria at near, which is well within normal limits and very likely does not in any way contribute to the symptoms.

The problem of aniseikonia is not so easily dismissed. This could not be the usual type of aniseikonia because, if it were, the symptoms would be present for a long time. the refractive errors might be expected to vary in both eyes, and vision would more likely be somewhat similar in the two eyes.

The patient read 20/50 "slowly." This indicates that 20/50 vision was possible through studying the letters and probably also that 20/70, while legible, was probably read hesitatingly and "slowly." The fact that metamorphopsia was also present suggests an explanation of the acquired aniseikonia. Metamorphopsia, when present in regard to letters, usually indicates an irregularity in the plane of the retina in the macular area, so that one is getting a distorted image that is comparable to the distorting effect of an irregularity in the surface of a mirror. The pinhole, by obstructing some of this area and thus removing interference, tends to diminish the distortion of letters. But the fact that vision does not come up to normal indicates that there is not only an irregularity of the surface, but also, that there is some damage to the retina. In this way one understands that an aniseikonia of an irregular type has been produced which is, in turn, producing binocular discomfort. This is particularly distressing to the patient for two reasons. First, a well-developed fusion sense does allow easy suspension of vision in this eye, and, secondly, the affected eye is her dominant eye. Thus, she is more disturbed than if it were the nondominant

eye that was affected. This may be compared to the embarrassment of a right-handed person who is suddenly required to use his left hand for precise work.

Therefore, the visual examination suggested some retinal pathologic change. It was found that the macular area showed an absence of the reflex and a peculiar marking of many irregular, small, yellowish areas which ordinarily are included under the general head of macular degeneration.

DIAGNOSIS

Macular changes, retina, right eye, producing metamorphopsia with binocular discomfort.

SOLUTION

All of these cases eventually are freed of symptoms through either of, or the combination of, two mechanisms: (1) the development of a compensatory suspension in the affected eye, removing the interference to binocular vision from its distorted image; (2) a diminution in the amount of metamorphopsia as the pathologic process resolves.

TREATMENT

Explain to the patient the cause of his discomfort. He may occlude the affected eye when reading (usually with the hand), since it is usually during reading that symptoms are really distressing; for the metamorphopsia is disturbing in precise imaging but is not noticeable when looking at gross objects.

QUESTIONS

House Officer: How did you determine that the right eye was the dominant eye?

Dr. Sloane: There are many tests. The one I used in this case was to have the patient make a circle with the first finger and thumb of both hands. The person then sighted the muscle light through this

circle. Then, by noting which eye was looking through the circle, the dominant eye was determined.

H. O.: Would the 20/50 vision, O.D., without the metamorphopsia give interference to the O.S. with its 20/20 vision so as to produce symptoms?

Dr. S.: Yes, the difference in visual acuity in two eyes which have so recently seen equally will tend to produce symptoms, and the metamorphopsia seems to cause more disturbing symptoms particularly at near.

243 Charles Street.

SOCIETY PROCEEDINGS

EDITED BY DR. DONALD J. LYLE

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

December 17, 1942

DR. ALFRED COWAN, *chairman*

EDWARD JACKSON, FOUNDER OF THE SECTION

DR. BURTON CHANCE delivered a memoir on this subject which was published in this Journal (January, 1943).

MEMOIR OF LUTHER C. PETER, M.D.

DR. EDMUND B. SPAETH presented this tribute, which will be published elsewhere.

MEMOIR OF WILLIAM T. SHOEMAKER, M.D.

DR. WILLIAM ZENTMAYER presented a paper on this subject which will be published elsewhere.

LIPAEMIA RETINALIS

DR. M. LUTHER KAUFFMAN presented two cases of lipaemia retinalis, both showing interesting and somewhat unusual findings. The first was not in a diabetic patient and was the third such case reported. This patient had suffered from chronic alcoholism for about two years, and also had had attacks of acute gastritis and vascular hypertension. In

the second case there were marked changes in the walls of the retinal vessels and severe retinosis complicating the diabetes.

Neither patient was in coma on admission. If any acidosis was present in either patient it was not revealed by the carbon-dioxide combining power of the blood or by the urinalysis; pH of the blood was not determined.

The reason for lipemia becoming visible in the retinal blood vessels naturally depended to some extent on the lipid content of the blood. Dr. Kaufmann suggested that another factor might be the size of the lipid particles, which become larger in the presence of chemical or electrolytic imbalance. The increase in the size of the particles would make the lipoids more easily visible through the vessel walls. The particles in an emulsion tend to coalesce and become larger in anything but the optimum medium for that emulsion.

Discussion. Dr. Eunice L. Stockwell reported a case of lipaemia retinalis seen several months ago. The patient was a 41-year-old man who was admitted to the hospital with a typical history of diabetes mellitus of four months' duration. He had had no insulin before his admission. Dr. Stockwell saw him on the day of his admission. His blood sugar was 301 and the blood cholesterol was 1,456; his carbon-dioxide volume was 60

percent. The fundus in each eye showed the typical picture of lipaemia retinalis, the veins being full, cream-colored in appearance, and white in the terminal branches. The arteries were flat and ribbonlike, and approached the veins in size and color.

The patient was placed on insulin that day and the following day the typical picture of lipaemia retinalis disappeared. Although the veins and arteries were still slightly pale and the blood cholesterol was 1,401, the vessels returned to normal color.

Dr. Alexander G. Fewell congratulated Dr. Kauffman for picking up a case of lipaemia retinalis in a nondiabetic. He said he had seen only two cases of lipaemia retinalis. He thought the condition was much more common than reported. The case reported by Dr. Stockwell was a typical case of lipaemia retinalis, but the retinal picture entirely disappeared within 48 hours.

Very little had been added to Heyl's original ophthalmologic observation in 1886. With two exceptions, all previously reported cases had been in diabetics. One exception was the case reported by Wagner in 1922. The patient was a nine-year-old boy who had undergone radium treatment for leukemia. The other was that of a poorly nourished child, aged one year, with an associated xanthomatosis and enlargement of the spleen. In nearly all of the reported cases there had been an associated acidosis, and, in quite a number, xanthomatosis. The acidosis in these cases was usually severe and of short duration, but it might extend over a long period of time and be comparatively mild, as reported in McKee's last case. In only a few instances had there been a careful chemical analysis of the blood with studies of the various blood lipoids. In general terms, it might be stated that lipaemia retinalis appeared when the value of the blood fat rose above 3.5 percent and disappeared when

it fell below 2.5 percent.

It had been suggested before that lipaemia retinalis was due to some condition other than the total amount of fat in the blood. This must be true, for a number of cases had been reported in which the fat content of the blood was high but no lipaemia retinalis was present. Before the discovery of insulin, practically all diabetic patients who developed lipaemia retinalis died in diabetic coma, but now with insulin these patients might live for many years.

Dr. I. S. Tassman asked Dr. Kauffman if he knew of any relationship between lipaemia retinalis and the white-cell count in these cases, especially since one case was reported by Wagner as occurring in leukemia. This brought up the question of whether the white count might have some relationship to the occurrence of lipaemia retinalis.

The other condition, such as xanthomatosis, was understandable because most of such cases were associated with diabetes; particularly those that occurred in young children in the form of the Schüller-Christian disease, which was a disease of the lipid metabolism.

Dr. M. Luther Kauffman, in closing, thanked the discussers for their contributions. Concerning acidosis he pointed out that even though the urine and all other findings were normal, the chemists showed that it was impossible to say an acidosis did not exist unless pH determination of the blood was made. This was called an uncompensated acidosis.

As Dr. A. Fewell pointed out, these cases might be much more common than the literature indicated. The way to discover them was to examine ophthalmologically everybody admitted to the medical service of the hospital. The ratio of phospholipins to total fat was a point to be considered in causing lipemia to become visible in the retinal vessels. It might also have an effect on the electrolytic balance. The chemists pointed out

that any change in the electrolytic balance would have a tendency to make these fat particles coalesce.

His male patient had a leukocyte count below 9,000 at all times. The girl's count ranged from 8,000 to 16,000 but she had had frequent infections. He did not believe that the leukocyte count was a factor in lipemia.

AN UNUSUAL CASE OF BIRTH INJURY OF THE EYE

DR. F. H. ADLER and DR. E. GERARD SMITH presented the case of a 33-year-old physician who had sustained a birth injury, which was evident today by a large depression over the left frontal arc. He was refracted in 1931 and the findings were as follows: R.E. $-2.50D.$ sph. $\ominus -0.50D.$ cyl. ax. 60° , vision 20/20; L.E. $-3.50D.$ sph. $\ominus -2.25D.$ cyl. ax. 180° , vision 20/20. In 1935 the refractive error was R.E. $-2.50D.$ sph. $\ominus -0.75D.$ cyl. ax. 50° ; L.E. $-2.75D.$ sph. $\ominus -2.75D.$ cyl. ax. 165° . The vision was 20/20 in each eye.

On reëxamination in 1938 the right eye was found to be about the same and the left had changed to $-1.00D.$ sph. $\ominus -2.75D.$ cyl. ax. 166° . Four years later the right eye showed little change but the left eye was now $-3.25D.$ cyl. ax. 166° . When last examined in 1942 the right eye again showed very little change. The left eye was found to be $+2.25D.$ sph. $\ominus -3.50D.$ cyl. ax. 170° . This represented, over a period of 10 years, a total change of 5.75 diopters. The vision was still 20/20 in the left eye after each refraction.

Examination of the eyes showed a left hypertropia with fixation with the left eye. The right eye turned down and in, the patient suppressing the vision in the right eye. Due to facial asymmetry the left eye was 5 mm. higher than the right. The rotations of both eyes were full in all directions except on the left, where there was some limitation of outward

movement. The right fissure was slightly wider than the left. The tension was 20 mm. Hg (Schiötz) in the right eye and 0 mm. Hg in the left eye.

Slitlamp examination of the right eye showed a few pigmented and nonpigmented deposits on the endothelium, but was otherwise negative. Examination of the left eye showed a marked chemosis of the conjunctiva of the whole lower cul-de-sac, limited to the lower bulbar conjunctiva. There were no signs of inflammation. There was a considerable amount of pigment on the anterior lens capsule, probably congenital in origin.

Ophthalmoscopic examination of the fundus of the right was negative. The fundus of the left eye showed slightly indefinite margins at the upper and lower poles of the disc. The retina showed some reflexes which were suggestive of retinal folds which may be due to an old retinal detachment.

Dr. Smith believed that the picture had a rational explanation. The globe might have been ruptured at birth. This rupture probably healed but may have left a fistula through which aqueous was escaping into the subconjunctiva and retro-retinal spaces, which would account for the chemosis of the conjunctiva and possibly a forward displacement of the retina. The latter was suggested by the change in refraction.

Dr. F. H. Adler said he was sure that Dr. Smith, and he, and their very obliging patient, would welcome any suggestion that anyone might have that would differ from this explanation. He had not been able to find in the literature a case that duplicated this, and the only possible explanation that had occurred to them was what Dr. Smith had given. The patient's tension was zero with the tonometer. Dr. Adler had always taught his students, and had read in the literature, that a tension of approximately 25 mm. Hg (Schiötz) was necessary for the maintenance of the optical properties of

the eye. This eye had a visual acuity of 6/6 in spite of zero tension.

Discussion. Dr. James S. Shipman asked Dr. Smith if he had a record of what his patient's tension was at first refraction.

Dr. H. Maxwell Langdon asked if it was not remarkable that this case remained quiescent for a number of years. As he understood it, about 10 years ago the eye began to develop peculiarities and the patient was now 34 years old. What had happened which produced this peculiar series of changes in the course of events? Did anything happen that could have caused an opening up of a fistula? He was not suggesting that there was a fistula there, but he just wondered what caused the drainage to start. Could it have been that the pressure on the globe in taking the finger tension caused the leakage of aqueous which apparently was taking place?

Dr. Alfred Cowan thought it did seem remarkable that this condition had progressed as described. Did not that seem unusual for an ordinary birth injury? In his experiences, birth injuries cleared up to a remarkable degree. It seemed from the appearance of the conditions which were considered to be due to birth injuries, that the eyes recovered to a much greater extent than if the same injury were sustained by an older person. So this case, if it really was a birth injury, was unusual in that it had become progressively worse.

Dr. Smith answered in regard to Dr. Shipman's question concerning what the tension was, that he got in touch with the men who examined the patient previously, and they told him his tension was normal when they examined him. With regard to Dr. Langdon's question about any injury, as far as he knew there was no subsequent injury. The patient did believe, however, that the chemosis below the cornea had always been present, to a greater or less degree.

PURTSCHER'S ANGIOPATHY TRAUMATICA RETINAE

DR. EDMUND B. SPAETH presented two cases of Purtscher's disease, one in abstract, the other in detail as to its clinical course.

The literature relative to this condition was discussed, for the etiology of the angiopathy is still not at all satisfactorily answered. This was reviewed in an attempt to determine, if possible, a consensus which might answer that question. The author himself suggested that fat embolism must be seriously considered as the possible cause of the retinal changes.

Discussion. Dr. James S. Shipman commented that this condition was not a recent discovery, having been described by Purtscher in 1910 in the case of a head injury. Even earlier than that, in 1900, Neck noted these fundus changes after compression or crush injuries of the chest. However, most of the literature on the subject was of European origin, and only in the past several years had it engaged the interest of American ophthalmologists. In a paper read before the American Ophthalmological Society and reported in the Archives of Ophthalmology in 1939, Bedell reviewed the literature; he had found 40 cases, and to these added 3 of his own.

In addition to the term "Purtscher's disease," the condition was also called "traumatic retinal angiopathy," "lymphorrhagia retinae," and most recently, "retinal teletraumatism." Knapp's "Medical ophthalmology," published in 1918, contained a description of the ophthalmoscopic picture, although it was given no definite name at that time. More modern textbooks included it under one of the above headings.

The usual history was a rather marked loss of vision in one or both eyes following a head injury, a compression injury of the chest or abdomen, or fractures of the vertebrae. The onset oc-

curred either immediately following the accident or the vision failed within a few days.

Externally there might be subconjunctival hemorrhages, often small, and ecchymosis of the eyelids and face as well as discoloration of the neck, chest, and upper extremities. There was no evidence of direct injury to the eye, such as laceration, nor was there any history of such injury.

Ophthalmoscopic examination revealed fairly typical fundus changes. Essentially, these were hemorrhages, exudates and edema, and dilatation of the retinal veins with constriction of the arteries. There might also be pallor of the disc, but more often this developed later when, in some cases, secondary optic atrophy ensued. A white appearance of the macular region had also been recorded as a late finding.

The hemorrhages might be small or massive, usually the latter. They might be flame-shaped or round. Most often they were found in the superficial layers of the retina, but a number of vitreous hemorrhages had been recorded. Stokes described a case in which there was such a massive hemorrhage in the macula that it had the appearance of "an island in a lake of blood." In addition, there was in *this case a round hemorrhage in the fovea*.

The edema and the exudates might be described together, these terms being ill defined by the various authors and in some instances, as in Bedell's paper, were used interchangeably. This was best shown by descriptions such as "the entire posterior pole was an immense milky white swelling covering the disc and retinal vessels" (Bedell); "a white, cloud-like plaque near the disc" (Bedell); "many discrete, elevated, whitish areas with round edges, some confluent, resembling cotton wool, and found along the superior and inferior temporal vessels" (Stokes). There might also be, as in the case presented by J. W. Smith, "a

diffuse dense cloud or veil in the posterior vitreous" which entirely obscured the fundus and which was considered secondary to the retinal pathology.

The changes in the caliber of the blood vessels, that is, the constriction of the arteries and dilatation of the veins, was similar to that seen in thrombosis of the central retinal vein. It might be added here that the exudates were often found along the course of the vessels; hemorrhages, when small, were apt to be seen along the retinal veins.

The secondary optic atrophy was not a constant finding. A great many of the cases reported had been followed for only a short time. However, Bedell had the opportunity of seeing a case 15 years after he had made the diagnosis of traumatic retinal angiopathy. The disc in this instance was waxy pale, the vision markedly reduced as one would expect.

The mechanism of production of the hemorrhages and exudates was not entirely known. Purtscher's theory was that head injuries induced compression of the spine in its longitudinal axis, which, in turn, produced increased intracranial pressure. This pressure forced the spinal fluid through the intervaginal space into the nerve head and along the retinal vessels, extravasating into the retinal tissue through the ruptured perivascular lymph spaces. However, since the intervaginal space is not a true cavity, this was hard to accept. Friedenwald believed, as did Urbanek and Loewenstein, that the changes are due to fat emboli. If this was true, it would seem that more of these cases should be seen following fractures of the long bones. Experimentally, Willers trephined the skulls of rabbits and found that the brain could be made to bulge through the hole when pressure was applied to the thorax or abdomen. Each of these theories partially explained the pathologic physiology; no one of them completely explained it.

There had been only one case in which

histologic sections of the eye were made and microscopically examined. This was reported by Savitsky and Gross in December, 1935, before the New York Neurological Society. They found "round structures within the retinal layers, more in the superficial, which reacted to the stains for fat." There was a division of opinion as to the clinical diagnosis, several ophthalmologists considering retinitis albens to be the true diagnosis rather than traumatic retinal angiopathy. For this reason it would seem unwise to accept the aforementioned pathologic picture as the usual one or as pathognomonic of the condition under discussion.

In none of the reports was any specific treatment suggested; treatment was not even mentioned. Presumably potassium iodide internally might be used to good effect.

The prognosis in these cases was variable. In a number of them there had been a return to normal vision, despite rather extensive retinal hemorrhages, exudates, and edema. However, secondary optic atrophy was always a threat in severe cases, and in others there had been reported permanent damage in the macular region consisting of fine dots and scattered pigment.

Dr. Edmund B. Spaeth said he had uncovered 51 relevant references, and these included some 70 cases. In regard to fat emboli, and the question which Dr. Shipman raised, was it possible that these were more probably the result of crushing injuries rather than otherwise? Injuries to the pelvis were not uncommonly followed by emboli and distant infarcts.

He did not believe that the histologic report mentioned was one of angiopathy traumatica retinae, and, with Dr. Shipman, he declined to accept that report as one for this condition.

Warren S. Reese,
Secretary.

NEW YORK SOCIETY FOR CLINICAL OPHTHALMOLOGY

December 7, 1942

DR. ISADORE GIVNER, *presiding*

SYMPOSIUM ON TROPICAL OPHTHALMOLOGY

THE INCIDENCE OF OCULAR DISEASES IN THE TROPICS

DR. BERNARD KRONENBERG spoke of the ocular diseases in the tropics, and tropical diseases which have ocular symptoms. He stated that tropical ophthalmology is interesting because of the wealth of material resulting from poverty, neglect, ignorance, and lack of medical attention. Special climatic and dietary factors were discussed. Brilliant light, wind, and dust cause a large number of complaints.

Actually there are very few ocular diseases to be found only in the tropics. Among these are loa loa, microfilaria, and onchocerciasis. Not all diseases are found in all geographic areas of the tropics. Some are limited to the African or Caribbean regions, and others to the Asiatic regions. Trachoma and vernal catarrh, although found in some of the tropics are not seen in Puerto Rico.

The diseases which have ocular symptoms are divided into three groups: (1) Those found only in the tropics; (2) those found primarily in the tropics but also in other areas of the world; and (3) diseases which occur in all areas but which are rather frequent in the tropics.

Under the first group he mentioned yaws, trypanosomiasis, and yellow fever. In the second group he mentioned dengue, relapsing fever, Weil's disease, leprosy, malaria, and intestinal parasites. Malaria was discussed in detail and attention was drawn to the necessity of differentiating between amblyopia due to quinine and

malarial optic neuritis. In the third group of diseases he discussed cholera, dysentery, and typhus. Another group discussed was vitamin deficiencies.

Common ocular diseases of the colder climatic areas also occur in the tropics. He pointed out that uveal diseases and cataracts were more common in the tropics. Congenital cataracts were seen more frequently on smaller islands where there was much intermarriage. Refractive errors show nothing unusual except an early presbyopia.

Preoperative care must pay special attention to dietary deficiencies and the common occurrence of syphilis and poor dental conditions. The postoperative care, because of the heat and humidity, must be a little different. Dressings must be changed more frequently.

In conclusion, he pointed out the definite existence of a field of tropical ophthalmology.

OCULAR ONCHOCERCIASIS

DR. EDWARD B. GRESSER said that onchocerciasis is an endemic roundworm infection found in widely separated tropic and subtropic foci, caused by the filaria of the genus *Onchocerca*, two species, *Onchocerca volvulus* and *caecutiens*, being parasitic for humans. The vector for human onchocerciasis is the biting black fly of the *Sulidae* family. The disease is of slow evolution, affects all ages, colors, sexes, and social stations, and is characterized by subcutaneous fibrous nodules or cysts located anywhere on the body and containing adult filaria. The mature filaria produce thousands of the markedly motile microfilaria which wander through superficial layers of the skin, accounting for the predisposition to ocular invasion with cysts above the neck line. Except when blindness occurs, the disease is neither debilitating nor disabling. The

blindness can be of any grade or extent, unilateral or bilateral.

The microfilaria invades every tissue and layer of the orbital contents. The living parasite produces mild reactions, but when dead and disintegrating, the reactions are marked. The process becomes intermittent and chronic with acute exacerbations. Photophobia, lacrimation, and discomfort are constant. Pain is hardly ever marked, circumcorneal injection is invariable, and a rather torpid kerato-iridocyclitis is the rule, although a keratitis or iritis may be present alone. With the slitlamp, the living parasite can be discerned in the bulbar conjunctiva, cornea, and anterior chamber.

Pigment granules are spread over the surface of the iris, and, collecting in the lower angle, form, with inflammatory products from the iritis, a partial brown ring and a mass which contracts and causes pupillary deformity. Synechiae with pupillary occlusion and seclusion, secondary cataract, and occasionally secondary glaucoma occur. There may also appear chorioretinitis with degeneration of the pigmentary epithelium and clumping of pigment without relation to the vessels. The corneal changes are remarkable: A superficial punctate keratitis of grayish dots, a fraction of a millimeter in diameter, is found in the deeper epithelium and the outer stromal layers and usually in the lateral parts of the cornea. This is transient or permanent and in protracted cases occurs in the deeper layers. The corneal epithelium in later stages is irregular from cell swelling, desquamation, and scarring. Fairly common is a limbal vascularization accompanied by connective-tissue sheaths and inflammatory cells anterior to and often replacing Bowman's membrane. Desmet's membrane frequently shows folds or dehiscences.

Accompanying the cyst formation and

ocular disease is a disseminated dermatitis characterized by induration with a greenish hue. This discoloration, noted in the western world but not in Africa, may be due to difference in skin pigmentation.

No cure is known for onchocerciasis. Chemotherapy has not proved effective in any form. Hyperthermia, of theoretical value, has not been used. Most of the success achieved has been through surgical removal of the cysts and adult worms, presenting production of the microfilaria, and in preventing reinfection.

Discussion. Dr. Harry Most said that despite the great emphasis between the type of disease occurring in the western hemisphere and Africa, it is doubtful whether there are two valid species of *Onchocerca*. The African and Mexican disease should be considered the same, caused by the same parasite.

The black fly, which is the vector, lays its eggs in water, sometimes at the bottom of streams. Eradication of these flies, breeding in fast-moving mountain streams, is such a difficult problem that most people in preventive medicine consider it hopeless. It resolves itself into educating people not to go to the streams to bathe in the daytime, and to keep covered, since this is a day-biting fly.

Treatment is not so hopeless as Dr. Gresser pointed out. For the most part it is impractical to remove the nodules from all patients. It has been shown that it is possible to inject the nodules with bichloride of mercury, hexylresorcinol, arsenicals, or gentian violet.

Dr. Gresser, in conclusion, replied that while the literature is replete with therapeutic procedures and promises of apparent cures, in the last analysis, nothing touches the adult filaria, whether by injection of the cyst or by intravenous administration of drugs.

EXPERIENCES IN AN EYE CLINIC IN THE CANAL ZONE

DR. G. G. MARSHALL told of his experiences while chief of the eye, ear, nose, and throat section of the Gorgas Hospital, commencing in November, 1917. He found that natives of the tropics became presbyopic at an earlier age than those of the temperate zone, but there was no greater frequency of cataracts, partly explainable by the relative youth of most of the patients seen. Pterygia were very frequent among the Negroes, and bilateral pterygia were not uncommon. Simple conjunctivitis, due to the tropical sun and dust in the dry season, was prevalent but not serious. Koch-Weeks infection was more severe and corneal ulcers were frequent. The population of the city of Panama was said to be 30 percent syphilitic, and extensive choroiditis and optic atrophy were very common. Careful exclusion of emigrant laborers with eye disease made trachoma very rare.

Night blindness was prone to develop in the malaria-infected Negro living on a deficient diet. These patients recovered in 10 to 20 days when given fresh milk, vegetables, and cod-liver oil. No cases of malaria came to Dr. Marshall's clinic for treatment as such.

Leishmaniasis has been found in Brazil and Panama and has various manifestations. In Central America it is characterized by ulcers of the nasal mucous membrane, from which the conjunctiva is infected, and then the cornea, causing severe keratitis. Plasticlike deposits are found on the cornea and perforating ulcers may result. There is ciliary congestion, pain, and photophobia.

Dr. Marshall visited a leper colony at Palo Seco and treated all stages of the disease. Facial-nerve paralysis, ptosis, and loss of brows and lashes were early symptoms. The iris and cornea are the least resistant parts of the eye. On the

iris are pearllike bodies containing the bacillus which may extend to occlude the pupil. The iris finally atrophies. Corneal involvement may be punctate, annular, or diffuse parenchymatous and may progress to blindness. The vitreous, choroid, retina, and optic nerve are involved late. Cataracts are frequent but extraction is of little value as by this time other conditions make the eye hopeless.

Discussion. Dr. Connor said that in a case of malaria developing amblyopia he prefers quinine to atabrine. He has never seen a case of blindness in which the patient remained blind from quinine; and even though the drug would be continued in small doses until he recovered, eventually the vision would return.

BIOMICROSCOPY IN TRACHOMA

DR. MILTON BERLINER said that the frequency of trachoma has so declined with the curtailment of immigration that the possibility of its presence may recede from the ophthalmologist's mind. While biomicroscopy has not made great contributions to the knowledge of trachoma, it has so correlated histologic changes with clinical findings as to permit early and differential diagnosis heretofore possible only by tissue examination.

Trachoma, like many other forms of chronic conjunctivitis, passes through the stages of hyperemia, neovascularization, papillary hypertrophy, and follicle formation. Neovascularization, following closely the hyperemia, is best seen in the tarsal conjunctiva at the beginning of inflammation or following prolonged mechanical irritation. Biomicroscopy shows small vascular tufts due to capillary proliferation from the normal vascular network just beneath the epithelium. The naked eye sees these as small red dots, easily mistaken for petechial hemorrhages, which may appear later. The organization

of the capillary tufts results in the formation of papillae which can be seen in outline upon vital staining with azur II, even before they cause surface excrescences. It is unknown whether some obscure chemotaxis or the firm attachment of the conjunctiva to the tarsus accounts for the appearance of these papillae in the tarsal rather than the bulbar conjunctiva. Follicles result from irritation causing lymphoid hyperplasia of the adenoidal layer of the tarsal conjunctiva. This reaction occurs in many viral, bacterial, and chemical conjunctivitis. Follicles and papillary hypertrophy may occur simultaneously and must be differentiated. The follicles are translucent protuberances between the papillae and are several times larger. There is a superficial vascular trellis-like network in contrast to the central vascular tuft in the papillae. Ordinarily follicles shrink and disappear in time, but in trachoma they are invaded by a fibroplastic process, forming scars. Ordinarily follicles are found in the lower lid and fornix, but in trachoma they are chiefly in the upper lid.

At the onset of trachoma, when only mild congestion is seen with the naked eye, biomicroscopy may reveal typical features. Cuénod and Nataf have presented an excellent analysis of trachoma. Even when only a pinkish conjunctival blush is seen grossly, with high magnification and optic section are found small reddish dots just beneath the epithelium which are distinguishable as the newly formed perpendicular vessels of the incipient papillae. At the same time the small, round, slightly protuberant pale follicles are beginning to appear. An infiltrative haze at the limbus and proliferation of the superficial limbal arcades are seen in the early stages of trachoma.

The velvety appearance of the conjunctiva is the most striking feature of the second stage. Each papilla appears to be

a tile of mosaiclike pattern which is differentiated from the papillary hypertrophy of benign conjunctivitis by the combination of papillae, follicles, and corneal involvement. Follicles may appear on the caruncle and semilunar fold. High magnification after vital staining with azur II exhibits bluish follicles and papillae outlined by dark-blue dots, the whole resembling a hexagonal mosaic.

Bleblike formations resembling small "sago-grains" occur, especially on the upper tarsal conjunctiva and caruncle. These result from proliferative epithelial downgrowth into the submucosa with the formation of pseudoglands.

Stage three commences with delicate white lines of scar tissue between the papillae, and cicatricial invasion between the absorbing ruptured or necrotic follicles producing stellate scars first visible under the biomicroscope.

In the fourth stage the increased scar tissue results in a smooth, avascular white surface. A horizontal white band, the superficial line of Arlt, develops in the middle of the tarsus. Contraction of the scar tissue leads to the dire sequelae which are due mainly to deformity of the eyelid or dryness of the eye following destruction of the secretory elements. Further, the accompanying pannus leads to loss of vision.

Biomicroscopic study shows pannus to be an early specific part of the disease, not a complication. Almost immediately after the onset there is an alteration of the limbal reluctance and vascularization which may be overlooked by ordinary methods of examination. Newly formed capillary loops extend in Bowman's zone. At this level many grayish points and lines produce a delicate haze. Within this area may appear small follicles, which, when, surrounded by a capillary network, form Herbert's rosettes. Follicles may be abortive or develop fully and then empty

and organize, leaving small epithelialized depressions, usually near the limbus, known as Herbert's marginal pits. Irregular facets follow the breakdown of small subepithelial infiltrations. The capillary loops progress downward with a relatively horizontal border preceded by a grayish area of faint infiltration. At first the pannus is superficial, but in severe cases there is destruction of Bowman's membrane with deep scarring and vascularization and irregular thinning of the entire cornea. Secondary degenerative changes, such as calcareous deposits, fatty hyaline degeneration, and keratectasia are found with pannus of long duration.

Discussion. Dr. L. A. Julianelle emphasized the stages of hyperemia, neovascularization, follicle formation, and papillary hypertrophy as merely the result of a prolonged low-grade stimulus. Consequently the diagnosis of trachoma before pannus or scar formation is difficult.

The cause of trachoma is a virus, although it differs in incubation period, course, and immunity from the usual virus diseases. The inclusion body, believed by Dr. Julianelle to be the virus, can be seen in scrapings from the upper tarsal conjunctiva, stained with Wright's stain, and permits early diagnosis. Most viruses have high tissue selectivity and, regardless of their mode of entering the body, invade a particular tissue. Trachoma, showing the greatest selectivity, enters the eye only by way of the eye and can affect only the epithelial cells of the anterior segment. When clinical signs or symptoms appear a full-blown case of virus infection is already present. This leaves two possibilities for treatment: to prevent the virus from entering the cell, and to kill it while it is in the cell. The latter is the basis for treating trachoma, and is difficult as it calls for an agent to enter the cell and kill the virus but not the cell itself. Trachoma burns out spontane-

ously, and scar tissue, which is not susceptible to the virus, is formed in the process. Curettage, silver nitrate, and copper induce scar formation. The sulfonamides have had success ranging from zero in Dr. Julianelle's hands to 100 percent in the Indian Service. He is not convinced that they are effective in trachoma.

Dr. E. Waldstein described his own personal case of trachoma to illustrate the possibility of an acute onset with profuse discharge. He had seen favorable reaction to sulfonamide medication, but admitted its concurrent use with other forms of treatment.

Dr. M. Jaffe asked whether incision of the conjunctiva at the limbus, then stripping it back and curretting the blood vessels to the pannus, resulted in increased transparency.

Dr. A. Braley stated that the Indian Service has found that practically all of its cases recover in a short time with sulfonamide therapy. Periodic scrapings show disappearance of the inclusion bodies while the patient is under treatment. In a series of over 200 patients at Fort Apache, 10 showed no improvement and approximately 10 others recurred. Treatment of another group led to the conclusion that without adequate or sufficiently prolonged administration of sulfonamide, good results cannot be expected. He had never seen a proved case of trachoma failing to respond to sulfanilamide.

Dr. G. Epstein asked whether there can be trachoma without pannus.

Dr. Berliner, in closing, said he had not seen spectacular results with the sulfa group. He had not performed peritomy with curettage but had transplanted mucous membrane at the limbus and also inserted catgut subconjunctivally and found little reaction in the conjunctiva at the limbus; there was some clearing of the superficial scars but not the deeper

ones. He said he has never seen trachoma without pannus.

Leon H. Ehrlich,
Secretary.

CHICAGO OPHTHALMOLOGICAL SOCIETY

December 21, 1942

DR. LOUIS G. HOFFMAN, *president*

SCIENTIFIC PROGRAM

THE STRUCTURE AND FUNCTION OF THE RETINA

DR. STEPHEN POLYAK (by invitation) presented a paper on this subject.

Discussion. Dr. S. Gifford and Dr. H. J. Smith discussed this paper.

KODACHROME CLINIC

DR. ROBERT VON DER HEYDT chose the following subjects for this presentation: 1. choroiditis; 2. rare clinical conditions; and 3. ocular trauma.

CLINICAL PROGRAM

(Presented by the Department of
Ophthalmology, University of
Chicago)

AVASCULAR INTERSTITIAL KERATITIS— QUESTIONABLE

DR. LOUIS ALKOFF presented R. B., a white boy, who was under treatment for congenital syphilis. He was brought to the Out-Patient Department on May 6, 1942, because of clouding of the cornea of the right eye. On examination, the vision could not be tested, but he could see people and objects at a distance. A faint circumcorneal flush was present in the right eye. The cornea showed a dense, deep, wedge-shaped opacity, with the base from the 7- to the 11-o'clock position. The cornea of the left eye showed a fainter similar opacity. Slitlamp examination re-

vealed edema of the posterior stroma with roughening of the anterior and posterior epithelial surfaces. There were no vessels.

During the next two weeks the left eye became as clouded as the right and the patient began to stumble. He was admitted to the hospital and given 10 injections of typhoid vaccine. The opacities began to shrink and become fainter until they just covered the vertex of the cornea in each eye. No vessels were present; the opacity was still in the deep stroma with roughening of the anterior and posterior surfaces.

RETINITIS PROLIFERANS, VITREOUS HEMORRHAGE, RETE MIRABILE OF THE RIGHT EYE; PERIPHERAL RETINAL HEMORRHAGE AND EXUDATE OF THE LEFT EYE

DR LOUIS ALKOFF said that C. K., a 42-year-old man, was first seen in October, 1942. The patient stated that two years ago he had suddenly seen black streaks before the right eye and his vision decreased immediately. He further stated that the vision in this eye had been 20/20 prior to that time. He was treated with O.T. injections for four weeks and the vision slowly improved. Since then he has had four similar episodes. There was also a history of sudden collapse of the right lung, for which he was treated with bed rest for nine months.

Vision, on admission, was R.E. 20/200, L.E. 20/13+1. The vitreous in the right eye showed many floaters, and the disc could hardly be seen. A dense white band of vascularized proliferating retinitis could be seen extending from the disc at the 2-o'clock position toward the temporal portion of the retina and vitreous. The macula was not seen. The fundus of the left eye was normal except for several small granular hemorrhages and irregular white exudative lesions, 6 disc diameters out in the periphery, at the 1-o'clock position. These were situated at the terminal

branches of the superior temporal artery.

Laboratory examinations showed no findings of significance. The patient was to be tested for brucellosis, since several members of his family have had it, and it is endemic in his community.

SYMPATHETIC OPHTHALMIA

DR. MAURICE DRELL said that J. O., a 64-year-old man who had been presented before the Society last year, had sustained an injury to the right eye in 1916, at which time a foreign body was removed. There had been recurrent pain and redness in the eye with general decrease in vision to perception of hand movements only at the time of the initial examination in July, 1941. Examination showed an iridocyclitis, complicated cataract, and an old scleral wound of the right eye. The left eye was clear.

Treatment consisted of the application of heat, atropine, and proteolac, but no marked change occurred until September 18, 1941, when he complained of pain in the left eye of five days' duration. The left eye showed an increased ray in the anterior chamber with cells, and engorged iris vessels. The left vision decreased from 20/20 to 20/50. The following day the symptoms had become more marked, and the pupil of the left eye had not dilated at all with atropine. The right eye was enucleated that day. On section this eye showed a typical sympathetic ophthalmia.

Since that time the vision of the left eye has improved to 20/16 but the patient has had a chronic iridocyclitis and a number of exacerbations and remissions. He has been treated with, and become sensitive to, atropine, scopolamine, homatropine, and duboisine. He has had salicylates, one course of neoarsphenamine, three courses of mapharsen, and the pupil has been kept dilated with 10-percent neosynephrin. The vision, at this time,

was corrected to 20/25+2 and he was able to carry on his work as a bartender.

ORBITAL NEOPLASM

DR. MAURICE DRELL said that J. D., a 44-year-old man, was first seen in 1935, when he had an otherwise asymptomatic exophthalmos of the right eye. Exophthalmometer readings were R.E. 23 mm., and L.E. 14 mm. There was some limitation of abduction and adduction of the right eye. The fundus and visual-field studies were negative. The chemistries, serologies, and urinalyses were negative; X-ray studies of the skull, orbits, optic foramina, and sinuses were also negative. The patient was seen by the Neurology Clinic, and a diagnosis of orbital tumor was made. Transfrontal exploration of the right orbit was performed but no lesion was found.

The patient returned in November, 1942, with an increase of protrusion of the right eye, and occasional redness after imbibition of alcohol. Exophthalmometer readings were R.E. 26 mm., and L.E. 15 mm. A mass was palpable below the superior nasal orbital margin; there was limitation of movement in all directions, especially superonasally; and some conjunctival congestion was present. Vision, with correction, was R.E. 20/200; L.E. 20/20. The fundus of the right eye showed some papilledema. The visual field studies showed enlargement of the blind spot and constriction of the lower temporal field of the right eye. X-ray studies showed what appeared to be a generalized decalcification of the posterior orbital wall, which was interpreted by the roentgenologist as secondary to the orbital neoplasm. An attempt was made at air injection of the orbit for further X-ray visualization, but upon insertion of the needle into the orbit, extravasation took place into the syringe, which suggested perhaps a vascular neoplasm. Further

local procedures were postponed until the extravasation should have become completely absorbed.

DIABETIC RETINOPATHY; BILATERAL RETE MIRABILE

DR. NORMAN TEPPER said that L. W., a 52-year-old woman, came to the clinic four months ago. Four days previously she had noticed a sudden decrease in the acuity of her vision, everything beyond a distance of 20 feet appeared as a "gray fog." Lights seemed to have a red ring around them, and she saw dancing black spots in front of her eyes.

Vision, with correction, was R.E. 20/50-1; L.E. 6/200. Tension, taken with a Schiötz tonometer, was normal. External examination was negative. A bilateral veil of vascular network was seen extending into the vitreous from the disc to +12. Some small hard exudates and a few faint macular hemorrhages were seen. Examination of the urine showed specific gravity 1.032 and 4+ sugar reduction.

One week later, following homatropine-paredrine refraction, vision was R.E. 20/40-2; L.E. 20/200. At the present time, four months after onset, corrected vision was R.E. 2/200; L.E. ability to count fingers at 3 feet. Light projection and perception and central fixation were good. Red and green were named correctly. The vascular tree was not elicited in either eye. No fundus details were visible. The rete mirabile was present in each eye. In the vitreous of the right eye, at the 2-o'clock position, was a hemorrhage which showed early organization.

OLD EXTENSIVE OCULAR TRAUMA

DR. WILLIAM ROSENBERG presented M.P., a 52-year-old man, whose complaint in September, 1942, was loss of vision in the left eye of 25 years' duration, and fogging of the vision in the right eye of

5 years' duration. Vision, R.E., was 20/25 with +3.50D. sph. \approx +2.00D. cyl. ax. 85°; L.E. 10/200, with good fixation and projection; red and green were easily identified and the vascular tree was elicited in that eye.

Twenty-five years ago some iron chips had entered his left eye. Attempts to remove them with a giant electric magnet were unsuccessful. Enucleation was advised but was not performed. X-ray studies were not made. Since that time he had felt that the left eye was useless, although the vision had cleared. In the past five years he had been aware of spots in front of the right eye which moved with the eye.

Examination under paredrine homatropine cycloplegia improved the vision in the right eye to 20/16-4 with +3.25D. sph. \approx +2.75D. cyl. ax. 90°. Vision in the left eye was improved to 20/16-3 with +11.25D. sph. \approx +1.50D. cyl. ax. 95°. The fundus of the right eye was normal; slitlamp examination showed three superficial punctate opacities on the corneal vertex of the right eye. Examination of the left eye showed a corneal pathway with a rent in Descemet's membrane at the 10:30-o'clock position, 2 mm. from the limbus, leading to a hole in the iris at the 11-o'clock position. The anterior chamber was clear, though a few wisps of vitreous extruded into the chamber nasally. There was iridodonesis; no lens substance was visible although remnants of the posterior capsule were seen. There were several fine vitreous opacities. In the superior nasal quadrant, corresponding to the superior nasal vortex-vein emissaries, there was a large area of choroidal sclerosis. X-ray pictures of the orbit revealed no foreign body. It had apparently dissolved. The patient was fitted with a minifying lens (Catmin) and has fusion on the synoptoscope.

The diagnosis was traumatic corneal opacity and rupture of Descemet's mem-

brane, hole in the iris, traumatic aphakia, traumatic superior nasal vortex-vein occlusion, and vitreous detachment, left eye.

CATARACTA COMPLICATA—ECTOPIA LENTIS

DR. WILLIAM ROSENBERG said that J. F. H., a 65-year-old man, gave a history of gradually decreasing vision for the past 15 years. He had been told that his vision was poor because of trauma, although he could recall only minor blows to his eyes. He was also told, seven years ago, that he had the beginning of a cataract in his right eye.

The vision in the right eye was 9/200; with the left eye he could count fingers at one foot. Light projection was quick and accurate and red and green were easily perceived. The vascular tree was elicited bilaterally. Examination showed marked bilateral iridodonesis with iris atrophy and bilateral dislocation of the lenses. Vitreous strands projected into the anterior chambers, and a foggy-white material was seen to surround the pupillary apertures. The pupils could be dilated only to 4 mm. The vision was improved R.E. to 20/50 with -4.50D. sph.; L.E. to 20/200 with -6.50D. sph. There was bilateral nuclear sclerosis. Many vitreous opacities were present in both eyes. The fundus of the left eye could not be seen. The fundus of the right eye, although somewhat atrophic, appeared to be otherwise normal. Visual field studies were normal. Medical and laboratory findings were essentially negative.

On June 28, 1942, a combined intracapsular loop extraction on the left eye was performed. The postoperative course was uneventful. Final manifest refraction improved the vision of the left eye to 20/30-3 with +9.75D. sph. \approx +3.50D. cyl. ax. 115°, and the patient was able to read newsprint rapidly with the addition of +3.00D. sph.

The diagnosis was bilateral subluxated

lenses, bilateral senile and complicated cataracts, and bilateral uveitis.

PERIVASCULITIS RETINAE

DR. BARBARA SPIRO presented E. S., a 31-year-old man, who in September, 1942, gave a history of the sudden appearance of a black streak in the upper visual field of his right eye, nine months previously. This cleared up in a day, and recurred six months later. He saw an eye physician who diagnosed an infected eye and treated him with injections. Five teeth were extracted to eliminate a possible focus of infection. There was no history of pain, redness, or tenderness of the eye.

The vision R.E. was 20/200, not improved under cycloplegic refraction; L.E. 20/13-4. The left eye was essentially normal. The vitreous of the right eye was hazy, containing a membranous opacity with dark-green nodules and black opacities. The vessels were thin and indistinct. A number of hemorrhages were seen around the macula and temporally in the periphery. A white mass, 1 P.D. in size, was observed temporal to the disc at the 9-o'clock position, with many small capillaries enmeshed in it. Similar masses were seen in the periphery. Slitlamp examination showed multiple golden deposits on the posterior surface of the cornea and in the anterior chamber and a few cells in the anterior vitreous.

Physical and laboratory findings showed no abnormalities. Two weeks later the vision in the right eye was 20/25 and the vitreous had cleared markedly. Four weeks later the vision was 20/16 and has remained so since. Vitreous floaters were still present and the fundus findings were the same except for the hazy vitreous.

The impression was that this patient had perivascularitis with proliferative retinitis. He was referred to the Neurologic Department, but no evidence of central-nervous-system involvement was found.

RETINAL DETACHMENT

DR. BARBARA SPIRO said that C. G., a 58-year-old woman, was first seen in April, 1942. She gave a history of having noticed flashes of light in her right eye in December, 1941. A diagnosis of detachment of the retina was made and she was treated with bed rest for three weeks. There was no history of injury to the eye.

Vision in the right eye was perception of hand movements at 4 feet, searching fixation, projection in all quadrants. Vision in the left eye was 20/13. The right eye was 10 degrees divergent. A total retinal detachment was found, extending to the disc; the highest point was seen with a +12.00 lens and the lowest point with a +8.00 lens. Old tears were present at the ora serrata and at the macula. The peripheral field of vision, taken with a flashlight, revealed a small area of vision in the upper nasal quadrant and one in the lower temporal quadrant.

Surgery was advised with poor prognosis because of long duration, completeness of the detachment, and the presence of the macular hole.

A microcoagulation detachment operation was performed on the right eye on April 27, 1942. The postoperative course was complicated by an acute upper respiratory infection. Three weeks later the retina was still elevated. Ten weeks later the retina appeared much flatter and the corrected vision was 20/200. The temporal and inferior operative reaction was more marked, with extensive pigment dispersion and white scarring. The peripheral field, taken with a 5/330 isopter, showed complete nasal constriction except for a 15-degree area surrounding the fixation point; there was about 25 degrees of temporal constriction.

Six months following operation, the corrected vision of the right eye was 20/50. The retina was fully attached, with a few faint folds in the macular area. There were some vitreous floaters,

5 years' duration. Vision, R.E., was 20/25 with +3.50D. sph. \approx +2.00D. cyl. ax. 85°; L.E. 10/200, with good fixation and projection; red and green were easily identified and the vascular tree was elicited in that eye.

Twenty-five years ago some iron chips had entered his left eye. Attempts to remove them with a giant electric magnet were unsuccessful. Enucleation was advised but was not performed. X-ray studies were not made. Since that time he had felt that the left eye was useless, although the vision had cleared. In the past five years he had been aware of spots in front of the right eye which moved with the eye.

Examination under paredrine homatropine cycloplegia improved the vision in the right eye to 20/16-4 with +3.25D. sph. \approx +2.75D. cyl. ax. 90°. Vision in the left eye was improved to 20/16-3 with +11.25D. sph. \approx +1.50D. cyl. ax. 95°. The fundus of the right eye was normal; slitlamp examination showed three superficial punctate opacities on the corneal vertex of the right eye. Examination of the left eye showed a corneal pathway with a rent in Descemet's membrane at the 10:30-o'clock position, 2 mm. from the limbus, leading to a hole in the iris at the 11-o'clock position. The anterior chamber was clear, though a few wisps of vitreous extruded into the chamber nasally. There was iridodonesis; no lens substance was visible although remnants of the posterior capsule were seen. There were several fine vitreous opacities. In the superior nasal quadrant, corresponding to the superior nasal vortex-vein emissaries, there was a large area of choroidal sclerosis. X-ray pictures of the orbit revealed no foreign body. It had apparently dissolved. The patient was fitted with a minifying lens (Catmin) and has fusion on the synoptoscope.

The diagnosis was traumatic corneal opacity and rupture of Descemet's mem-

brane, hole in the iris, traumatic aphakia, traumatic superior nasal vortex-vein occlusion, and vitreous detachment, left eye.

CATARACTA COMPLICATA—ECTOPIA LENTIS

DR. WILLIAM ROSENBERG said that J. F. H., a 65-year-old man, gave a history of gradually decreasing vision for the past 15 years. He had been told that his vision was poor because of trauma, although he could recall only minor blows to his eyes. He was also told, seven years ago, that he had the beginning of a cataract in his right eye.

The vision in the right eye was 9/200; with the left eye he could count fingers at one foot. Light projection was quick and accurate and red and green were easily perceived. Vitreous strands projected into the anterior chambers, and a foggy-white material was seen to surround the pupillary apertures. The pupils could be dilated only to 4 mm. The vision was improved R.E. to 20/50 with -4.50D. sph.; L.E. to 20/200 with -6.50D. sph. There was bilateral nuclear sclerosis. Many vitreous opacities were present in both eyes. The fundus of the left eye could not be seen. The fundus of the right eye, although somewhat atrophic, appeared to be otherwise normal. Visual field studies were normal. Medical and laboratory findings were essentially negative.

On June 28, 1942, a combined intracapsular loop extraction on the left eye was performed. The postoperative course was uneventful. Final manifest refraction improved the vision of the left eye to 20/30-3 with +9.75D. sph. \approx +3.50D. cyl. ax. 115°, and the patient was able to read newsprint rapidly with the addition of +3.00D. sph.

The diagnosis was bilateral subluxated

lenses, bilateral senile and complicated cataracts, and bilateral uveitis.

PERIVASCULITIS RETINAE

DR. BARBARA SPIRO presented E. S., a 31-year-old man, who in September, 1942, gave a history of the sudden appearance of a black streak in the upper visual field of his right eye, nine months previously. This cleared up in a day, and recurred six months later. He saw an eye physician who diagnosed an infected eye and treated him with injections. Five teeth were extracted to eliminate a possible focus of infection. There was no history of pain, redness, or tenderness of the eye.

The vision R.E. was 20/200, not improved under cycloplegic refraction; L.E. 20/13-4. The left eye was essentially normal. The vitreous of the right eye was hazy, containing a membranous opacity with dark-green nodules and black opacities. The vessels were thin and indistinct. A number of hemorrhages were seen around the macula and temporally in the periphery. A white mass, 1 P.D. in size, was observed temporal to the disc at the 9-o'clock position, with many small capillaries enmeshed in it. Similar masses were seen in the periphery. Slitlamp examination showed multiple golden deposits on the posterior surface of the cornea and in the anterior chamber and a few cells in the anterior vitreous.

Physical and laboratory findings showed no abnormalities. Two weeks later the vision in the right eye was 20/25 and the vitreous had cleared markedly. Four weeks later the vision was 20/16 and has remained so since. Vitreous floaters were still present and the fundus findings were the same except for the hazy vitreous.

The impression was that this patient had perivascularitis with proliferative retinitis. He was referred to the Neurologic Department, but no evidence of central-nervous-system involvement was found.

RETINAL DETACHMENT

DR. BARBARA SPIRO said that C. G., a 58-year-old woman, was first seen in April, 1942. She gave a history of having noticed flashes of light in her right eye in December, 1941. A diagnosis of detachment of the retina was made and she was treated with bed rest for three weeks. There was no history of injury to the eye.

Vision in the right eye was perception of hand movements at 4 feet, searching fixation, projection in all quadrants. Vision in the left eye was 20/13. The right eye was 10 degrees divergent. A total retinal detachment was found, extending to the disc; the highest point was seen with a +12.00 lens and the lowest point with a +8.00 lens. Old tears were present at the ora serrata and at the macula. The peripheral field of vision, taken with a flashlight, revealed a small area of vision in the upper nasal quadrant and one in the lower temporal quadrant.

Surgery was advised with poor prognosis because of long duration, completeness of the detachment, and the presence of the macular hole.

A microcoagulation detachment operation was performed on the right eye on April 27, 1942. The postoperative course was complicated by an acute upper respiratory infection. Three weeks later the retina was still elevated. Ten weeks later the retina appeared much flatter and the corrected vision was 20/200. The temporal and inferior operative reaction was more marked, with extensive pigment dispersion and white scarring. The peripheral field, taken with a 5/330 isopter, showed complete nasal constriction except for a 15-degree area surrounding the fixation point; there was about 25 degrees of temporal constriction.

Six months following operation, the corrected vision of the right eye was 20/50. The retina was fully attached, with a few faint folds in the macular area. There were some vitreous floaters,

but the patient complained only of diplopia.

IMPLANTATION CYST

DR. G. HENRY MUNDT said that this patient, a 66-year-old white man, came to the Clinic in November, 1938, and stated that a cataract extraction had been performed on the left eye seven years previously and on the right eye five years previously, in Italy.

Vision R.E. was 0.4; L.E. 1.0 (corrected). The following findings were noted: chronic trachoma, both eyes; bilateral aphakia; bilateral pterygium; iridectomy, left eye; and corneal nebulae. The tension was normal in each eye. Slit-lamp examination showed proliferated epithelium and multiple yellow crystals in the posterior lens capsule of the left eye.

When the patient returned in March,

1941, a lesion filled with fluid was noted at the 9-o'clock position on the iris of the left eye, approximately 3 to 4 mm. in size. The pterygium was removed from the right eye. In May, 1941, he complained of tearing of the left eye. Fluorescein passed through the punctum and tear duct into the nose without difficulty.

He was observed at monthly intervals, receiving treatment for trachoma. In August, 1942, the corrected vision was R.E. 20/50, L.E. counting fingers at 6 feet. He still complained of tearing. Slitlamp examination showed epithelial proliferation over the surface of the posterior capsule, with several small cystic areas. The cyst on the iris had increased in size. A diagnosis of implantation cyst, in addition to a finding of Elschnig's pearls, was made, and X-ray therapy was advised.

Post, 640 South Kingshighway, Saint Louis 10, Missouri*; Society Proceedings to *Dr. Donald J. Lyle, 904 Carew Tower, Cincinnati 2, Ohio*. Manuscripts should be typed in double space, with wide margins.

Exchange copies of medical journals should be sent to *Dr. William H. Crisp, 530 Metropolitan Building, Denver, Colorado*.

Subscriptions, applications for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 837 Carew Tower, Cincinnati 2, Ohio*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Miss Emma S. Buss, 5428 Delmar Boulevard, Saint Louis 12, Missouri*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-548 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

TREACHERY IN OPTICS

We are told that the fighting forces of the United States now number something like ten million. Generally speaking, these men represent perhaps the finest assembly of physical manhood that the world has ever seen. Many of them, unfortunately, will never return to their homes.

In combat, whether of land, sea, or sky, much depends upon the visual efficiency of this great body of fighters and auxiliaries. Some of them have been accepted for service in spite of the fact that their visual acuity without correction is a good deal short of normal, and that their effi-

ciency must depend chiefly upon the wearing of correcting lenses. But in certain fighting services no significant degree of optical defect is tolerated. The requirements for officers of the Army and Navy are considerably higher than for the rank and file. The standards for the Navy and Marines are higher than those for the Army. Most exacting of all are the visual conditions laid down for the Air services.

As to every branch there is good reason for the visual standards prescribed. In all walks of life we are familiar with the handicaps created by imperfect ocular function. The schoolboy who reads badly

may do so either because of actual inability to see or because he has an eye fatigue which reduces his power of visual and mental concentration. Poor vision or eye fatigue in a workman is not infrequently responsible for injury or death to the man himself or to those around him. In like fashion, imperfect visual function may result in death and disaster among the armed forces.

Applicants for jobs with railroads or other industrial concerns often resort to special tricks in order to deceive the examiner. Sometimes they are successful, and by their scheming have added to the industrial hazard. The penalty paid by the individual, the organization, or the community may be serious.

The applicant for a special line of activity in the fighting forces may be shocked to find that he does not meet the visual requirements. It may be that he is genuinely desirous of giving the utmost possible service to his country in the emergency. Perhaps he would rather be an officer than a private, rather an air pilot than a ground worker. Frequently his first reaction is that the visual standard is unduly strict, that he is experiencing a personal injustice, and that the rule represents an obstacle which he should attempt to overcome. He forgets that such rules have usually been created out of the lessons of experience.

Somewhere around the recruiting station, or elsewhere, the disappointed applicant encounters someone who assures him that a certain "doctor" knows how to cure such optical imperfections. The candidate thinks the matter over and proceeds to visit the so-called "doctor," who, for anywhere from fifty to a couple of hundred dollars, undertakes to put the patient in a position to hurdle the service barrier. Usually, all the candidate gets for his money is disappointment and disgust, but now and then, either through devious

methods or by the aid of certain mechanical "exercises" which stimulate a temporary forcing of accommodative or muscular adjustment, he succeeds in passing the test.

What happens to such a candidate? His inadequacy may be disclosed at some later stage of induction or training. Or he may have the good luck, especially if otherwise possessed of the best possible mental and physical equipment, to do valuable and efficient service. But he faces the risk that a visual breakdown, at some critical moment, will work mischief to himself and others.

It must be remembered that not only does bodily fatigue have a marked capacity to reduce ocular efficiency in the presence of a refractive or muscular defect, but eyestrain itself not infrequently causes general fatigue, with incidental reduction in central control. The hyperope, the astigmatic subject, even the myope who when in the pink of condition is able to force his visual apparatus to its peak of achievement, may find his efficiency seriously impaired in times of weariness or crisis. His hurdling of the visual barrier may then render him rather a liability than an asset to the armed forces.

Certain claims have been made as to ability to overcome, by training, the ordinary imperfections of red-green color vision. But careful research clearly indicates that any apparent success in this direction has been spurious and has depended upon acquiring, by infinite repetition, an extreme familiarity with the arrangement of a series of cards used in the testing of color vision. The individual who had gone through such a course of training would be just as likely to prove dangerous as any other victim of red-green color-blindness.

The man who has to undergo special training in order to cross the boundary line of visual requirement for a special

service would be wiser and more patriotic to give up the attempt to enter that service. If he maneuvers his way in, he may be a potential traitor to his country. Much more specifically may the accusation of treachery be applied to the pseudo-professional tricksters who fatten on this sort of enterprise.

W. H. Crisp.

EXERCISES TO IMPROVE VISION

Day by day the ophthalmologist is placed in an increasingly difficult position by his young patients and their parents who have heard tales of miraculous improvement of vision among their friends and acquaintances by eye exercises. Two groups are especially urgent, young men who desire to be enrolled in officers' training classes and whose vision is insufficient to meet the requirements of the armed branches in which they are interested, and, secondly, myopic girls who want good vision without glasses.

Most ophthalmologists for a long time "pooh-poohed" the idea that anything could possibly be done to help the visual acuity of these young myopic people except the prescribing of glasses. The fairly numerous cases in which visual training of one type or another has enabled a man to pass visual tests previously impossible for him are forcing the eye physician to give thought to the matter. The ever-recurring question is whether there is merit in this training that is being given. Is the visual acuity truly increased or is it the acquisition of accessory skills that gives success in those patients who do learn to read smaller letters on the vision chart? Do better psychologic approaches, the learning of tricks, or even the increased facility usually acquired by constant practice account for the results? The physician wants to know how frequently improvement can be obtained and

how this is accomplished. Most doctors have neither the time nor the inclination to study the matter through for themselves, so they either tell their patients that they have no faith in these so-called exercises or that they must seek elsewhere if they want to try them.

In most large cities there are those who are giving these exercises. They tell the prospective patient that they may not be able to accomplish anything, thus putting the responsibility on the individual and furnishing themselves an easy excuse if success is not attained, and all at a very good price.

Undoubtedly ophthalmologists have turned a deaf ear to this physiopsychologic approach to the problem of sight. The concept is so different from that taught in standard textbooks on refraction, and the theory and methods of procedure have not even appeared in ophthalmologists' literature, that they are largely hearsay to most eye physicians. To them there seems something iconoclastic, almost heretical, in disregarding the dioptric system and considering the eye merely as a link in the path of the image to the brain, a link of practically limitless potentialities unless the eye is definitely pathologic.

Perhaps the ophthalmologist does not really want to believe that it is possible to improve vision materially by these methods. He has heard that they are enormously time-consuming, requiring from five to six hours of patient training daily for many weeks, and furthermore he fears that to learn the technique, supposing that it were truly worthwhile, would require much time and effort. Oculists have seen a marked turning toward orthoptics in recent years, and most of them have disliked giving the training. Then there has been the rise of the controversial subject of aniseikonia with its very special type of examination and unusual lenses. Eye

physicians may dislike to contemplate the possibility of another expansion of visual care.

The ophthalmologist now wants to know just what value there is in this training to improve vision. He is very, very skeptical and desires to move cautiously. How can this information be obtained? There seem to be two methods. First and most satisfactory would be carefully conducted clinical experiments. The set-up for this is complicated and expensive. It really necessitates the employment of technicians familiar with the methods of training generally used who must be paid, and the coöperation of ophthalmologists who are willing to give the necessary time to supervise, check, and criticize. Then, too, there must be willing and interested subjects for the experiment and an adequate set-up of suitable instruments, all very elaborate and costly; but, fortunately, this study is apparently soon to be undertaken in at least two places in this country, so that in a reasonable length of time the harassed ophthalmologist may expect some sort of an answer to his questions.

A second criterion on these so-called exercises may sometimes be made by the oculist on his own patients, if he can maintain friendly relations with those giving the training and will encourage his patients to return to him for systematic checks. The writer has been able to do this in a few cases, thus far without having found any material improvement in the subjects, but these are admittedly unfavorable patients with relatively high myopia and many of them have not followed out the prescribed treatment fully, especially not having given the necessary time to it. Most of those who claim to have had success with this training try to insist on almost full-time work over many weeks, whereas most patients want to continue concurrently other activities, such

as school, and do the exercises in their spare moments only.

The type of pseudomyopia in which overefforts of accommodation, especially in reading, produce an associated convergence spasm, seems the only type that should reasonably yield to relaxation therapy, but this kind definitely should respond and it is probably on the favorable reaction of this fairly numerous group that most of the good reports rest.

Another point of view with regard to this visual training is presented in the first editorial in this issue, a viewpoint that certainly warrants careful consideration and is one more reason for attempting to arrive at some conclusion in the matter.

Lawrence T. Post.

BOOK NOTICE

AN INTRODUCTION TO CLINICAL PERIMETRY. By H. M. Traquair, M.D., F.R.C.S. 4th edition. Clothbound, 332 pages, 245 illustrations and 3 colored plates. London, H. Kimpton, 1942. Price \$6.50.

This fourth edition of Traquair's highly regarded book, making its appearance in a war year, shows some change in its make-up, but little alteration in the text (see review of third edition, this Journal, 1938, v. 21, p. 1049). The book, as before, consists of 12 chapters. The early part of the book presents Traquair's classical concept of the nature and significance of the field of vision, forming the basis for the "quantitative" approach to perimetry. The second half of the book is a systematic description of the perimetric changes produced by disease of each part of the visual mechanism.

Several clinical entities receive a more thorough exposition in this new edition. Among these are a more careful elucidation

tion of the types of perimetric changes shown in Jensen's chorioretinitis juxtapapillaris; a description of the Foster-Kennedy syndrome; and a paragraph on optico-chiasmic arachnoiditis.

The portion of the Appendix dealing with the "Anatomical relations of the visual pathway" (section III; also sections IV and V) has always seemed, to this reviewer, to be of paramount importance in the appreciation of the perimetric changes for each part of the visual mechanism. The inclusion of eight new figures helps to focus the reader's attention on this section. They facilitate the organization of these anatomic relations into a mental picture which is necessary to the proper evaluation of the text. It is to be hoped that future editions will further emphasize this topographic-anatomic section.

This new edition is printed on thinner, less glossy paper, and there has been a reduction in over-all size, weight, and, best of all price.

Benjamin Milder.

OBITUARIES

AN APPRECIATION OF ALFRED VOGT 1879-1943

With the passing of Prof. Alfred Vogt, of Zürich, ophthalmology has suffered the loss of one who without a doubt has made the greatest contribution to ocular clinical diagnosis during the past quarter of a century.

His early studies of radiant energy and spectral analysis centered mainly on experimental work on the effects of ultraviolet and infrared light on ocular structures. The injurious effects of infrared light in industry and the possibility that with it cataracts could be made to order were disclosed. He showed the relative innocence of ultraviolet light, the sup-

posed damaging effect of which, in his own words, had always been the "whipping-boy" in ophthalmologic literature.

Vogt's development of filters of copper sulphate and erioviridin B which, with an arc light as source of illumination, allowed of the examination of the fundus with red-free light, was a great advance in ocular diagnosis (1913).

By means of this illumination the yellow coloration of the macula could be observed in the living eye. There is an increased visibility of the nerve-fiber striation and in the reflection of retinal folds. The minute blood vessels could be followed practically into the macula. The progression of macular vacuole formation could be better observed. Macular pigment changes, especially the diagnosis of fresh pigment formation, which is yellow, may be differentiated from small black hemorrhages. In order to have a complete elimination of all red a microarc light had to be the initial source of illumination, as the filters excluded 97 percent of the light, leaving but 3 percent for observation.

The use of the older type of ophthalmoscope with mirror was necessary. Effort was made by manufacturers to circumvent these important necessities by building filters into the various types of electric ophthalmoscopes. This resulted in a semi-red-free illumination, thus defeating the real value of Vogt's method. Among Professor Vogt's publications are two monographs on red-free light.

His first "Atlas of slit lamp microscopy of the living eye" was published in four languages: German, English, French, and Italian (1921).

The second edition presented his life work, appearing in three large volumes (1930, 1932, 1942). The many thousands of colored illustrations were a monumental artistic achievement, not as yet equaled.

His book on the "Pathogenesis and operative therapy of retinal detachment" (1936) was a timely follow-up of the work of his fellow Swiss countryman Gonin.

During three decades ophthalmologic and medical journals continually carried a steady stream of Vogt's new contributions.

His investigation in genetic biology and on heredity culminated in the publication of an intensive study of senile changes in identical twins (*Klinische Monatsblätter für Augenheilkunde*, April, 1938). This contributed much of confirmative value to our knowledge of the many new evidences of ocular senility which he disclosed by the use of the slitlamp.

Among the many new uses of the latter was his utilization of the reflection of light on delimiting ocular surfaces. It allowed of a visibility of the individual endothelial cells on the posterior corneal surface. Here, and in this way only, individual living fixed cells may be seen.

Most important and of immense practical clinical value was Vogt's introduction of the very narrow slitlamp beam (1918-20), the utilization of an extremely thin optical cross-cut section. By means of this method the beam if well focused allowed of an accurate determination of depth within media. Thickenings as well as thinnings in certain areas of the cornea could be seen and compared. The topographic anatomy and histology of the lens, its nuclear zones and lamellae were accurately seen for the first time by means of this narrow beam. It also allowed of an exact determination of the ages of the many concentric nuclear zones.

Previous to these refinements slitlamp observation was limited to focal illumination and transillumination. These, however, disclosed such a wealth of new, heretofore unknown clinical pictures that many were astounded to observe this

new world and were much enlightened. Hence the well-focused narrowed-beam refinement, with its increased possibilities, was usually overlooked, except by Vogt's disciples and followers. These, however, are obtaining a maximum of valuable clinical information.

A new era, bringing inestimable diagnostic possibilities as well as an interesting office diversion, has been the happy fate of Professor Vogt's followers. The use of the slitlamp at an expense of but little time has taught the art of accurate observation.

In 1939 his associates and friends from all over the world had published a *Festschrift* containing almost 100 articles to commemorate his sixtieth birthday.

He told me of his kidney involvement 20 years ago. In spite of this progressive affliction he had kept up a prodigious amount of clinical work, painstaking investigations, and had conducted a large private practice, drawn from all over the world.

So again, another ophthalmologic giant has passed on to immortality.

Robert von der Heydt.

SANFORD R. GIFFORD 1892-1944

American science in general and Chicago ophthalmology in particular suffered a grievous loss in the all too untimely death of Sanford R. Gifford on the twenty-fifth of February of this year. Up to eight days before, he had been feeling well, although extremely tired from the enormous overload of his University and private work. Four days later he entered the Passavant Hospital in a serious condition, and finally succumbed to pneumonia. In accordance with his expressed wish, a simple funeral service was held.

Sanford R. Gifford, born in Omaha on January 8, 1892, was the son of an

equally famous father, Harold Gifford, who left a great imprint upon American ophthalmology. His undergraduate collegiate work was completed at Cornell University, where he majored in literature. Later he received an M.A. degree from the University of Nebraska, and his M.D. degree from the same school in 1918. Following a short internship in Wise Memorial Hospital in Omaha, he enlisted in the Army and was assigned as bacteriologist to Base Hospital 49 in Allery, France, with the University of Nebraska Unit, and later served with the Army of Occupation.

After his discharge from the Army, he went to the Nebraska Methodist Hospital, in Omaha, for a two-year internship, and then entered practice with his father in that city, and at the same time was active in the University Ophthalmic Clinic. He spent the year of 1923 studying in various clinics and centers in Europe, including the Augenlinik in Freiburg, under Professor Axenfeld; at the Tübingen and Vienna clinics; with Morax in Paris; and at Moorfields in London. Publications of both clinical and investigative work began to flow from his pen, and soon the ophthalmologic profession became aware that there was another and greater Gifford on the horizon. In 1929 he was called to the Chair of Ophthalmology in Northwestern University Medical School, and shortly thereafter moved his residence to Chicago. Omaha's loss was Chicago's gain, for his ability and personality soon put him among the leaders of the profession.

There were four separate aspects to Dr. Gifford's professional life: his clinical work, his investigative work, his teaching, and his private practice; and I believe that subconsciously his interest rated them in that order. Although a research man of the first order, he was primarily a clinician, and as such his experience

and judgment commanded national respect. His ophthalmic surgery was bold, and he pioneered in many fields of ocular therapy, but the safety and integrity of the eye under his knife was his first consideration. From a therapeutic standpoint, Sanford Gifford was undoubtedly the leader in this country, not only by his own work, but even more through his

Sanford Robinson Gifford, M.D.

outstanding "Handbook of ocular therapeutics." Even before his advent into medicine, he exhibited the mental curiosity of a true research man. He always wanted to know the why and wherefore of a problem, and that attitude led to some of his major investigative publications. The following are indicative of the scope of his work in this field:

Biochemistry of the lens. With Drs. J. E. Lebensohn and I. S. Puntenney: *Archives of Ophthalmology*, 1932, v. 8, p. 414; and *American Journal of Ophthalmology*, 1933, v. 16, p. 1050.

Visual sensation produced by roentgen and radium rays. With E. E. Barth: *Archives of Ophthalmology*, 1934, v. 11, p. 81.

Reaction of buffer solutions and of ophthalmic drugs. *Archives of Ophthalmology*, 1935, v. 13, p. 78.

Filtration experiments with the virus of inclusion blennorrhoea. With E. B. Tilden: *Archives of Ophthalmology*, 1936, v. 16, p. 51.

Tendon transplantation for paralysis of the external rectus muscle. *Archives of Ophthalmology*, 1940, v. 24, November.

Central angiospastic retinopathy. *Archives of Ophthalmology*, 1939, v. 21, February.

Dr. Gifford was perhaps somewhat too impatient to be the ideal undergraduate teacher, but as a teacher of graduate students who approached his own mental level, he had no peer. Still his "Textbook of ophthalmology" for undergraduates is one of the outstanding manuals of its type; only those of May and Parsons are comparable. Under his inspired leadership the Department of Ophthalmology at Northwestern has done much to further the knowledge of this specialty among physicians in general practice. Furthermore, he had that rare gift of developing a "school" of young men, imbued with his ideals and following in his footsteps. Private practice was somewhat of a chore, although he enjoyed the human contacts involved, as well as the diagnostic problems associated with a large referred practice.

Sandy Gifford was the best "company" that a person could hope to have. Uniformly cheerful, he could always see the quirks in a situation, which he could usually top with an appropriate quip. He was very well read, especially in general science, and his memory was of the encyclopedic type. The French and German languages were second nature to him, and during the first Pan-American Con-

gress of Ophthalmology, he delivered an impromptu speech in Spanish from the floor of the meeting. I well remember his earnest, albeit somewhat abortive attempts to master Arabic while we were attending the International Congress of Ophthalmology in Egypt, in 1937. Written English was quite a hobby, and he belonged to a literary society in Chicago, before which he delivered his famous essay on "Garlic and horseblankets," a masterpiece of analysis of the patients he saw in Omaha during his earlier days.

A very happy home life was his lot. Alice Carter Gifford maintained a smooth-functioning household and was the ideal helpmate for Sandy. The oldest son, Sanford, a graduate psychiatrist, is now in the Army, and the younger son, Carter, an undergraduate architectural student, is on duty with the Seabees.

We are going to miss Sandy more and more as time goes on. His influence on Chicago ophthalmology was great and was of that type that cannot be replaced easily. But for those of us who had the happiness of his friendship, there is a great void, an emptiness that his passing has left. Our sorrow is that of self-pity, for we think of Sandy and the joy that he gave us as The Immortal Bard has put it into the mouth of Claudius, King of Denmark,

"That we with wisest sorrow think on him
Together with remembrance of ourselves."

Harry S. Gradle.

ABSTRACT DEPARTMENT

EDITED BY DR. WILLIAM H. CRISP

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

3

PHYSIOLOGIC OPTICS, REFRACTION, AND COLOR VISION

Luckiesh, Matthew. Test charts representing a variety of visual tasks. *Amer. Jour. Ophth.*, 1944, v. 27, March, pp. 270-275. (2 figures, 1 table, references.)

Messenger, H. K. Principles of refraction. *Med. Clinics North America*, 1942, v. 26, Sept., pp. 1595-1614.

The first half of this paper is a review of the basic principles of refraction, under the following headings: rays; object and image points, focus; the measurement of vergence; a simple means of calculating the distance of an image; the forms of an ophthalmic lens; refraction of the eye. The second half of the paper offers "a simple subjective method" for the correction of refractive errors, dealing with the determination of axis, cylinder, and sphere. (13 figures.) W. H. Crisp.

Pascal, J. I. A rational basis for cross-cylinder tests. *Amer. Jour. Ophth.*, 1944, v. 27, March, pp. 280-281.

Pascal, J. I. Simple transposition of obliquely crossed cylinders. *Dis. Eye, Ear, Nose, and Throat*, 1942, v. 2, Nov., p. 349.

The author points out the practical usefulness of learning to transpose obliquely crossed cylinders to give insight into cross-cylinder work and cylindrical corrections generally. The mathematical method of accomplishing this transposition is explained.

Robert N. Shaffer.

Solandt, D. Y., and Best, C. H. The Royal Canadian Navy color-vision test lantern. *Canadian Med. Assoc. Jour.*, 1943, v. 48, Jan., p. 18.

The construction of the Royal Canadian Navy color-vision-test lantern is described. It presents to the patient two white or colored lights which give a dimensional representation of the riding lights of a vessel with a beam of 25 feet at 2,000 yards. Various combinations can be used. By its use some 30 percent of those failing in the Ishihara test will pass. The authors think a large percentage of such patients have

strictly normal color vision, and that the others are anomalous trichromates with only slight defects. Test procedures are outlined and the evaluation of data obtained is discussed.

Robert N. Shaffer.

Sugar, H. S. Binocular refraction with cross-cylinder technique. *Arch. of Ophth.*, 1944, v. 31, Jan., pp. 34-42.

Many persons who wear corrective lenses the prescription for which has been determined by accurate monocular refraction are uncomfortable during binocular vision. In many cases, says the author, the trouble is due to changes in the astigmatic axes when both eyes are used together for distant vision and during convergence accommodation. The paper analyzes such changes in a small series of 70 normal eyes with astigmatism of 1.00 D. or more, and explains the use of the cross cylinder to determine these changes under binocular fixation. All the patients had binocular single vision. Four explanations have been advanced; namely, lenticular changes, fusional compensation, torsional movements of the globe, and action of the extrinsic muscles in changing the curvature of the cornea.

The author has used the cross cylinder not only for binocular determination of the axis of cylinders for distance, but, more recently, for binocular determination of the axis of astigmatism for near vision when reading glasses alone were required. A table shows the change in axis from monocular to binocular testing as found in many cases.

As an additional conception in the attempt to get comfort with the binocular correction in difficult cases, the author takes up the subject of spherical equivalent. The spherical equivalent of a

compound lens system corresponds to the dioptric midpoint of the interval of Sturm. Numerically, the spherical equivalent of a compound lens system in plus-plus or minus-minus combinations is equal to the spherical power of the system plus half the power of the cylinder. The spherical equivalent of a simple cylinder is equal to half the power of the cylinder.

A series of case reports is given showing the application of the spherical equivalent. The following combinations all have the same spherical equivalent: - 2.75 D. sph. + 2.00 D. cyl. axis 100°; - 2.50 D. sph. + 1.50 D. cyl. axis 100°; - 2.25 D. sph. + 1.00 D. cyl. axis 100°; - 2.00 D. sph. + 0.50 D. cyl. axis 100°.

In a given case these combinations were tried in the order listed. The most comfortable combination may be tried in a trial frame in the waiting room for a half hour as a test. In this particular case the third combination gave comfort and was prescribed. The visual acuity with this system was 20/25. (5 charts, references.)

R. W. Danielson.

4

OCULAR MOVEMENTS.

Berens, C., and Romaine, H. H. Post-operative cicatricial strabismus: results of the transplantation of Tenon's capsule. *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1943, 47th mtg., Jan.-Feb., pp. 183-205.

This study was carried out in rabbits, using various techniques. The grafts used were free, pedicle, and apron; the substances, Tenon's capsule, amnioplastin, egg membrane, and peritoneum. Adhesions were produced by manipulation, scarification, and abrasion of the muscle with an instrument.

Pedicle grafts produced the best results. The apron graft apparently forms a tunnel in which the muscle acquires greater motility. Amnioplastin, egg membrane, and peritoneum were found unsatisfactory as substitutes for Tenon's capsule. Rough manipulation of the muscles or capsule produced adhesions, so that it is important to exercise the greatest care to avoid trauma to these structures. Reaction from suturing and from suture material should be avoided if possible. A suture material, nylon (6-0), has been used very successfully. In cases of complete fixation of the muscle to the sclera, transplantation of Tenon's capsule definitely improves motility.

Clinical reports of four typical cases are presented. Case 1 records a good result in postoperative cicatricial exotropia, case 2 a bad result in postoperative cicatricial exotropia, case 3 a good result in cicatricial exotropia following a second transplantation of Tenon's capsule in a patient whose cosmetic appearance and functional result had been worse after the first transplantation of Tenon's capsule, case 4 a good result in postoperative cicatricial esotropia. A table showing the findings in the 21 operations is included. (6 tables, 9 illustrations.)

Gertrude S. Hausmann.

Davis, W. T. Differential diagnosis of paresis of the obliques and the superior and inferior recti muscles. *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1943, 47th mtg., Jan.-Feb., pp. 206-209.

This paper was illustrated by a film, depicting the various types of paralysis of the ocular muscles. Until Bielschowsky formulated the differential diagnostic signs between palsy of the superior and inferior recti and the obliques, paresis of the vertically acting recti

was frequently confused with that of the obliques. The outstanding differences are as follows: In palsy of the right superior oblique or of the left superior rectus, if the patient looks up and left there is a high amount of right hyperphoria, from overaction of the right inferior oblique. In palsy of the right superior oblique, if the head is tilted toward the right shoulder, there is little or no vertical deviation. In palsy of the right superior rectus no change in vertical deviation occurs on tilting the head toward either the right or the left shoulder.

Gertrude S. Hausmann.

Foster, J., Pemberton, E. C., and Freedman, S. S. Graded squint operations. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 320-329.

The authors tabulate the results obtained with the number of millimeters of recession or resection and the degree of squint corrected. The operations were carried out under general anesthesia up to 14 years of age, and under local anesthesia above that age.

One-mm. recession of the internal rectus produced an average of 2.9° correction. One recession in four produced a surprise result, and squints which were variable prior to operation remained variable after operation. The unintended vertical displacement obtained in a simple recession or advancement could not be controlled by raising or lowering the insertion of a horizontal muscle. (3 tables, 1 diagram, references.)

Beulah Cushman.

Guibor, G. P. Recession of the inferior-oblique muscle from the external-rectus approach. *Amer. Jour. Ophth.*, 1944, v. 27, March, pp. 254-257. (13 illustrations, references.)

Harris, Wilfred. **Ataxic nystagmus. A pathognomonic sign in disseminated sclerosis.** *Brit. Jour. Ophth.*, 1944, v. 28, Jan., pp. 40-42.

The author reports a condition he calls ataxic nystagmus. The eyes turned laterally and the conjugate action appeared weak. The right eye, when looking toward the left side, did not reach the inner canthus. At the same time the left eye showed a coarse nystagmus, as though outward movement could not be maintained because of weakness. Usually the nystagmus of the left eye continued as long as the patient looked to the left, the right eye remaining stationary in its position short of the inner canthus. It was this discrepancy between the movements of the two eyes which suggested the term "ataxic nystagmus." Three case reports are given. Beulah Cushman.

Lynn, Beatrice. **The treatment of concomitant and latent squint.** *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 344-351.

The author outlines the results obtained five years after the inauguration of an orthoptic department in two hospitals. The steps in the treatment were estimation of the error of refraction, occlusion to prevent or overcome amblyopia exanopsia, establishment of simultaneous macular perception, increasing power of fusion, and correction of deviation (by operation, if necessary), together with version and vergence exercises and stereoscopic vision.

Among the stimulating exercises advised for suppression is frequent attendance of the cinema or teaching by cine-projectors, because the amblyopic eye sees moving objects more easily than stationary ones. Observations seem to demonstrate that if a child has

a squint before the age of two years it is unlikely that fusion will be established, but it is of vital importance to prevent amblyopia and to increase the lateral movement of each eye. Suppression must be overcome before a strong sense of fusion can be established. When this has been done, operative procedures may be undertaken and exercises resumed. (One table, 3 diagrams.) Beulah Cushman.

Spaeth, E. B. **Congenital blepharoptosis—a classification. The principles of surgical correction.** *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1943, 47th mtg., March-April, pp. 285-300.

The importance of early diagnosis and treatment of congenital ptosis is stressed. Of the cases here discussed, 37 percent were complicated by such symptoms as muscle imbalance and torticollis, loss of vision either single or binocular, curvature of the spine, and spasm of the occipitofrontalis. The cases are divided into nine groups: (1) unilateral ptosis without involvement of the superior rectus muscle, (2) unilateral ptosis with involvement of the homolateral superior rectus muscle, (3) bilateral ptosis without involvement of the superior rectus muscle, (4) bilateral ptosis with involvement of the superior rectus muscle, (5) unilateral ptosis with weakness of both superior recti muscles more marked in the homolateral eye, (6) ptosis with more or less complete third-nerve and even sixth-nerve paralysis, (7) ptosis with the classical jaw-winking reflex, (8) ptosis with Duane's retraction syndrome, (9) ptosis with neurofibromatosis. The three main principles to be considered in surgery for correction of ptosis, all of them necessary at various times in these cases, are: use of the occipitofrontalis, use of the superior

CONJUNCTIVA

Perkins, J. E., Korns, R. F., and Westphal, R. S. Epidemiology of epidemic keratoconjunctivitis. *Amer. Jour. Pub. Health*, 1943, v. 33, Oct., pp. 1187-1198.

During five months beginning September, 1942, an extensive epidemic of keratoconjunctivitis was studied in a Schenectady factory. For military reasons, the names and the number of cases involved are not given. Approximately 4 percent of the entire personnel were affected, and of these 56.1 percent showed the disease in both eyes and 85.5 percent developed corneal opacities. In only 19 percent had the corneal opacities disappeared at the end of two months. The peak of the epidemic was reached five weeks after onset, and after this the epidemic subsided gradually until the thirteenth week, when a slight increase again occurred. The groups most affected were first physicians and nurses, and next, employees exposed to ocular foreign bodies. A higher rate was also noted in firemen who slept in dormitories. Secondary cases in the households of those affected were approximately 4.9 percent, most frequent in adult females and milder in children. The cause is probably a virus transmitted from person to person (respiratory?). Only a small percentage of those exposed, however, develop clinical symptoms. The virulence of the virus, the amount of exposure, and the resistance of the host are apparently the factors which determine who will be infected and how severely. A rigid aseptic technique was employed, consisting of washing hands routinely between patients, using a separate sterilized dropper for each pa-

rectus muscle (if normal) and shortening of the levator. General ptoses, classified under 1, 2, 4, 5, and very occasionally 9, are best corrected by levator advancement with usually partial tarsectomy. Ptosis classified under 3 is the ideal indication for the Mottais-Parinaud technique. For ptosis classified under 6, early extraocular muscle surgery is important. It should be completed before the ptosis itself is corrected. For ptosis classified under 7 and 8 a complete tenotomy with tenectomy of the levator should be followed several weeks later by a Reese orbicularis transplant to the occipitofrontalis. Ptosis classified under 9 should usually be corrected by a Hess procedure. (21 illustrations.)

Gertrude S. Hausmann.

Wheeler, J. R. A review of the treatment of concomitant and latent strabismus. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 353-356.

Binocular vision, a late acquisition in phylogeny, can only be acquired postnatally. Binocular coördination probably develops between three and six months of age, but may not be stable for a number of months. From 18 months to two years development proceeds rapidly, and by six years of age binocular coördination is firmly established. Rarely does so-called concomitant strabismus commence after that age. The later the squint develops the better the prognosis. The author states that his aim in treating concomitant strabismus is to obtain two eyes cosmetically straight, and with good binocular vision. As causes of concomitant squint he cites physical defects, fusion defects, refractive errors, and sometimes a psychologic factor.

Terrizzano, M. F., and Terrizzano, A. J. M. Tuberculous keratoconjunctivitis treated with roentgen therapy. *La Semana Med.*, 1944, v. 51, Jan. 6, pp. 22-23.

The patient was a girl of 13 years. The disturbance involved the cornea and the conjunctiva of the right upper eyelid. Biopsy from the conjunctiva showed numerous tuberculous follicles. The interstitial keratitis was sufficiently dense to prevent a view of the iris, and the vision was reduced to light perception. Enucleation was recommended but refused. Four roentgen irradiations were given in the course of a month, each of 200 r. One similar treatment was given the next month, two in the third month, two in the fourth month, and one each in the fifth and sixth months of treatment. Eleven months after the treatment was initiated the vision of this eye had returned to normal, although there were two small corneal leucomas.

W. H. Crisp.

Wold, K. C. Epidemic keratoconjunctivitis. *Minnesota Med.*, 1944, v. 27, Jan., p. 25.

Epidemic keratoconjunctivitis is to our knowledge a virus disease characterized by an acute conjunctivitis, lid edema, lack of purulent discharge, preauricular adenopathy, and in some cases the appearance of corneal maculas which occasionally reduce visual acuity for a period of several months. Treatment is mainly symptomatic, although the use of convalescent serum or early small doses of X ray have in some cases seemed to influence the otherwise self-limited course of the disease.

Robson, J. M. Experimental corneal ulcers. *Brit. Jour. Ophth.*, 1944, v. 28, Jan., pp. 15-25.

A résumé of the production of corneal ulcers and the application of treatment at the different stages of ulcer formation is given. The ulcers were developed by injection of *B. pyocyaneus*, *pneumococcus*, *staphylococcus aureus*, *hemolytic streptococcus*, and the human and bovine strains of the *tubercle bacillus*.

The work was started in 1940 for the purpose of investigating experimental mustard-gas lesions on the eye and their treatment. It was found that secondary infection played an important part in determining the severity of the lesions. Local treatment with chemotherapeutic agents decreased the severity of the primary reaction and also the tendency of the rabbit eyes to develop delayed vascularized keratitis. The infections produced by different types of organisms could be influenced by chemotherapeutic agents and antiseptics. The methods of administration of such drugs are compared. UVEAL TRACT, SYMPATHETIC DISEASE AND AQUEOUS HUMOR

Leathart, P. W. Parasympathetic iridoplegia. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 306-308.

The author uses the term parasympathetic iridoplegia to describe a condition which he has found at rare intervals following purulent sinusitis. The pupil on the side of the sinusitis is widely dilated and will not contract to light or convergence; and the near vision is blurred. The extrinsic ocular muscles and optic nerve are unaffected. The condition is exactly opposite to that found in Horner's syndrome. The lesion is located in the region of the ethmoid sinus, and involves the constrictor and convergence reflex arcs after the afferent and efferent limbs have left the third-nerve nucleus. Recovery has occurred in a few weeks without other treatment than eserine, and leaving no disability. (One diagram.)

Lowenstein, O., and Levine, A. S. 5. Pupillographic studies (periodic sympathetic spasm and relaxation, and role of sympathetic nervous system in pupillary innervation). *Arch. of Ophth.*, 1944, v. 31, Jan., pp. 74-94.

This paper presents detailed pupillographic study of a woman patient aged 22 years, with a syndrome of periodic sympathetic spasm and subsequent re-

laxation. Part of the time the eyes were under normal conditions and at other times they were under the effects of various drugs. The patient suffered from a progressive degenerative condition of the central nervous system, characterized by gradual development of motor and sensory disturbances, peculiar gait and periodic spastic extension at the wrist and flexion of the ulnar three fingers, which preceded by some seconds the periodic pupillary phenomena.

Impulses traveling over the sympathetic pathways produce pupillary dilatation consisting of several dilatation phases at an average speed of 0.4 mm. per second, followed by contraction at an average speed of about 0.07 mm. per second. The primary interval in the present case was 2 mm.

The light reflex of the pupil, usually considered parasympathetic, contains in its phase of contraction some factors, which are determined by the functional state of the sympathetic system, whereas the primary phase of contraction depends predominantly on the parasympathetic system. When the secondary and tertiary phases in contraction are weak, cocaine will improve them.

When the pupil is contracted with physostigmine and the primary phase of contraction is poor, it can be improved by sympathetic spasm resulting from neutralization of physostigmine by epinephrine. When the pupil becomes small because of poor sympathetic innervation, hypersensitivity to cocaine and hyposensitivity to physostigmine develop. Conversely, when the pupil becomes large under the influence of hyperinnervation by the sympathetic system, hypersensitivity to physostigmine and hyposensitivity to cocaine develop. (12 figures, references.)

Ray, B. S., Hinsey, J. C., and Geohegan, W. A. **Observations on the distribution of the sympathetic nerves to the pupil and upper extremity as determined by stimulation of the anterior roots in man.** *Annals of Surg.*, 1943, v. 118, Oct., p. 647.

Knowledge of the preganglionic sympathetic outflow to the upper extremity and pupil of man has been incomplete because of deductions from indirect methods and experimental observations of laboratory animals. In a series of 18 patients in whom the cervicothoracic region of the spinal cord was exposed and the anterior nerve roots were electrically stimulated, the following observations were made: In ten patients changes in the pupil showed that sympathetic innervation traveled through one or more roots between levels of cervical 8 and thoracic 4. In 16 patients in whom preganglionic innervation to the hand was investigated it was found that there was variation in the upper and lower levels within limits of the first and tenth thoracic. After division of all anterior roots containing sympathetic fibers to the hand there was a return of sympathetic activity within ten weeks. This may indicate a functional reorganization through other pathways. The observations emphasize the necessity for recognizing the variability in the levels of sympathetic control to the upper extremity and pupil in man.

GLAUCOMA AND OCULAR TENSION

Evans, P. J. **A note on iridencleisis.** *Brit. Jour. Ophth.*, 1943, v. 27, Dec., pp. 548-550.

The author describes his modification of the operation of iridencleisis. He states that it is indicated in cases of noncongestive glaucoma, either chronic or subacute. If the iris is still elastic and the pupil responsive to eserine, the author makes a peripheral iridectomy by an oblique incision including only about two thirds of the withdrawn iris, but sufficiently long to provide a tongue which will reach the subconjunctival pouch through the lips of the incision. The temporal pillar is repositioned into the anterior chamber, while the nasal pillar is included in the lips of the incision. The final result retains the sphincter action of the pupil and provides an adequate fistula. Gentle massage and 0.5-percent pilocarpine are used for one to three months following the operative procedure. (2 illustrations.) Beulah Cushman.

CRYSTALLINE LENS

Dunlap, L. G. **Safety in cataract extraction.** *Trans. Pacific Coast Oto-Ophth. Soc.*, 1942, v. 27, pp. 150-155. (See *Amer. Jour. Ophth.*, 1943, v. 26, Nov., p. 1242.)

Foster, J. **Preoperative cultures and antisepsis.** *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 329-335. (See Section 2, Therapeutics and operations.)

Samuels, B. Pathologic changes in the lens associated with nontraumatic iritis. *Arch. of Ophth.*, 1944, v. 31, Jan., pp. 8-17; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41.

The author had described in one previous article the structural changes in a lens during the active stage of a corneal ulcer; and, in a second paper, the changes that may result long after an ulcer has been replaced by scar tissue. The present paper deals with the microscopic study of lesions occurring in a lens in nontraumatic iritis. Ordinarily a lens remains clear after a first attack of iritis. It is only after repeated attacks that opacities appear in the lens. In this study, microscopic examination was made of the lenses from twenty globes with nontraumatic iritis. A majority of the globes had been enucleated because of tuberculosis of the uvea, usually of the conglomerate type. In two globes cysticercus was discovered; one had been involved in sympathetic ophthalmia, and in one a retinoblastoma was present. In one globe the condition was mistakenly diagnosed as retinoblastoma, and two specimens showed syphilitic iritis.

In six cases in which iritis had been severe there was evidence of coincident glaucoma. In fourteen cases the capsule showed ruffling and folds. In many specimens it was noted that the disintegration of lens fibers seemed to have antedated proliferation of the epithelial cells. (8 figures, references.)

RETINA AND VITREOUS

Agatston, S. A. Clinical analysis of fifty cases of diabetic retinitis. *Med. Record*, 1943, v. 156, Aug., p. 482; Sept., p. 553.

The author surveys fifty cases of diabetic retinitis. The duration and severity of diabetes are not definitely related to the retinitis, nor does complete control of diabetes arrest the retinitis. Absence of changes in retinal veins and arteries is a favorable prognostic sign. The author thinks the first sign of retinitis is not lipid exudate but petechial capillary hemorrhage. Venular and capillary pathology offers the most logical explanation of fundus pictures, because the advanced retinal changes are so frequently out of proportion to existing arterial or renal disease. The presence of engorged retinal veins indicates a tendency to thrombosis with danger of large hemorrhages. Such changes render an eye unfavorable for intraocular surgery, because of the probability of postoperative hemorrhage.

Robert N. Shaffer.

Berens, Conrad. An illuminated retractor for eye operations, especially for detachment of the retina. *Amer. Jour. Ophth.*, 1944, v. 27, March, p. 281. (One figure.)

Black, G. W. Detachment of the retina. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, p. 311.

The author reports a case of bilateral detachment of the retina treated by the Guist operation upon the right eye in 1933, and in which in 1940 extracapsular lens extraction was performed on the same eye with final visual acuity of 6/24 with +5.00 sphere.

Dickson, W. E. C., Pritchard, G. C., Savin, L. H., and Sorsby, A. Two cases of visible emboli in retinal arteries. *Brit. Jour. Ophth.*, 1944, v. 28, Jan., pp. 1-14.

The author gives two cases of visible

obstruction of retinal arteries. For one case histologic illustrations were obtained. In one case there was a heart lesion with vegetations, complicated by embolic processes, in the absence of arteriosclerotic changes or thrombus formation. (19 illustrations.)

Beulah Cushman.

Eisaman, J. L. **Chronic occlusive arterial disease (arteriosclerosis obliterans), associated with retinitis pigmentosa.** *Amer. Heart Jour.*, 1943, v. 26, Dec., p. 836.

A 56-year-old male gave a history of chronic occlusive arterial disease affecting particularly the lower extremities. Associated with this condition there was a typical picture of retinitis pigmentosa with no apparent familial background. This case suggests that pathologic changes may not be localized in the retina but may occur as a part of a similar disorder elsewhere in the body.

Owen C. Dickson.

Gifford, S. R. **Proliferating retinopathy in diabetes.** *Quarterly Bull. Northwestern Univ. Med. School*, 1943, v. 17, Winter Quarter, p. 252.

The contrast between ordinary diabetic retinopathy and proliferating diabetic retinopathy is pointed out. The author thinks the larger retinal veins are involved in the latter condition and that thrombosis of these veins may be the precipitating factor. The only case the author has seen from its onset was initiated by vitreous hemorrhages, followed by the usual blood-vessel and connective-tissue invasion of the vitreous.

In four cases out of six studied, increased capillary fragility was found. Cases with proliferating retinopathy are more likely to develop gangrene, and vice versa, showing that both have changes in the peripheral vessels. Gif-

ford points out the similarity between this condition and retinal periphlebitis. It is suggested that in all such cases careful study of the peripheral circulation be made, including pressor tests, heparin clearance, capillary fragility, and estimation of blood ascorbic-acid. The author concludes: "It is conceivable that if such tests were employed in every serious case of diabetes, the development of this tragic ocular condition might be prevented."

Robert N. Shaffer.

Gifford, S. R., Bauman, L., Jacobi, H. G., and Berens, C. **Symposium on diabetic retinitis.** *Amer. Jour. Digestive Dis.*, 1943, v. 10, Sept., pp. 329-339.

Gifford: In the largest group of retinal retinopathies the basic picture is of small round deep hemorrhages with small white discrete deposits in and about the central area. Frequently superimposed are fine flame-shaped hemorrhages in the nerve-fiber layer, usually due to associated vascular sclerosis. A second group of retinopathies is characterized by large, often preretinal, hemorrhages, usually followed by a variable new-vessel and connective-tissue formation. A third group presents retinal venous thrombosis.

Diabetic retinopathies are more frequent in older patients, and are not proportionate to the severity of the diabetes but to its duration. Ascorbic acid and vitamin-B complex do not improve the ocular condition because they do not cure the capillary fragility. Citrin, when available, should be tried.

Bauman: Hypertension is an aggravating factor in the production of diabetic retinopathies. Retinopathies are very frequently accompanied by gangrene and other foot complications of diabetes. Both result from sclerosis of the peripheral arteries with interference

of circulation, and both are largely preventable. Lack of restraint and coöperation is the principal cause of poor control in diabetes. Protamine zinc insulin alone or combined with ordinary insulin controls most patients. A new product, globin insulin, which apparently has the advantages of both, will soon be on the market.

Jacobi: Glycosuria and polyuria are harmful because they disturb the electrolyte balance. Too rigid diet restriction may be just as harmful as excessive laxity. A mild glycosuria may not be harmful in the elderly or arteriosclerotic diabetic, being a safety measure against insulin shock. Retinal lipemia and similar lesions are much less frequent with a low-fat régime.

Berens: No single ophthalmoscopic sign is pathognomonic of diabetes, although perimacular and other retinal changes are suggestive. Hypertension is apparently not the principal cause of retinal hemorrhages in diabetics. Bacteria and metabolic toxins may be factors. In patients with increased capillary fragility no improvement has followed the use of vitamin-B complex and ascorbic acid. Charles A. Bahn.

Leopold, I. H. **Diabetic retinopathy.** *Arch. of Ophth.*, 1944, v. 31, Jan., pp. 96-101.

This review of the literature discusses the etiology of diabetic retinopathy under the headings of hyperglycemia, vascular status, vitamin therapy, endocrine glands, and chemical constituents of the blood, especially fat.

Diabetic retinopathy has been variously attributed to uncontrolled hyperglycemia prior to administration of insulin (with the suggestion that the retinopathy is essentially a capillary disease).

Other special fields of study, here re-

viewed, include: dilatation of the retinal veins with production of punctate hemorrhages; experimental work as to the role of the endocrine glands in diabetes; and fat metabolism in relation to therapy. (Bibliography.)

Lewis, E. M. **Angiomatosis retinae** (successful treatment of one case). *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1943, 47th mtg., May-June, pp. 354-363. (See *Amer. Jour. Ophth.*, 1943, v. 26, Dec., p. 1347.)

Lijo Pavia, J. **Detachment; reattachment; tears and cyst of the retina.** *Rev. Oto-Neuro. Oft.*, 1942, v. 17, Oct., pp. 107-117. (See *Amer. Jour. Ophth.*, 1943, v. 26, June, p. 644.)

Newton, F. H., and Schade, A. H. **An experiment to determine the conservation of vitamin A in the eye under strain.** *Ohio State Med. Jour.*, 1943, v. 39, Sept., p. 827.

The authors assume that night blindness is associated with vitamin-A deficiency and that soft tones on the walls of some industrial plants reduce eye fatigue. Six female employees whose work required very sustained and accurate fixation under artificial light were dark-adapted for two minutes, then subjected to a powerful light for two minutes, and then placed in the dark again, with a view to testing regeneration of the visual purple. Those who worked under a Verd-A ray lamp claimed to feel less fatigued than those who worked under a frosted lamp. In two cases with excessive eye fatigue, two hundred thousand units of vitamin A were given for a week. Less fatigue was then experienced, and the eyes felt more comfortable with a Verd-A lamp than with a frosted lamp. (Graphs.)

Charles A. Bahn.

Sal Lence, J. **Specular pulsatile zones of the vitreous.** Arch. de la Soc. Oft. Hisp. Amer., 1942, v. 1, Oct., pp. 336-338.

With the aid of the Gullstrand ophthalmoscope, and examination of the eyes of more than 1,450 school children, the author has been able to observe brilliant reflexes in the fundus, especially along the veins. These reflexes are caused, according to the author, by internal reflection of the beam of light in the framework of the vitreous. Contrasted with the pulse of the retinal arteries, which is only present in certain pathologic conditions, the pulse of the reflexes described is a constant finding, especially in the eyes of young people; and its absence would indicate a pathological condition.

Ramón Castroviejo.

Wahrsinger, P. B. **Severe pre-eclampsia with separation of the retina.** Amer. Jour. Obstet. and Gynecology, 1943, v. 46, Oct., p. 371.

Appearance of retinal separation in severe pre-eclampsia is extremely infrequent but has been noted on several occasions. The author presents the following case: A 33-year-old woman, in her second pregnancy, was seen during the fourth month of gestation. All examinations were normal. The previous pregnancy had ended in spontaneous abortion. During the eighth month the patient was examined at home. She gave a history of nausea and vomiting of 24 hours duration, and an episode of temporary blindness. There was marked edema of face, conjunctivas, hands, legs, and ankles. The blood pressure was 195/110 mm. Upon hospital admission, urinalysis showed hyaline and granular casts. Sedatives, glucose, Karell diet, and Strognoff treatment were used. Ophthalmoscopic examina-

tion showed: right eye large retinal detachment in nasal half of fundus; small detachment below the optic nerve; left eye, large retinal detachment above and a small detachment below the optic nerve. The retinas and the margins of the optic nerves of both eyes were edematous, the margins of the discs blurred, the arteries narrowed. Retinal detachments and edema of the retina were probably due to subretinal and intraretinal transudates. The second day after Cesarean section, the edema of the retina subsided, but the detachments were of the same size. On the twelfth day post partum, the vision cleared and the blood pressure was 150/80 mm. Six weeks post partum, there was complete recovery from the retinal detachments. All findings were normal, the blood pressure 120/80 mm. The diagnosis was: severe pre-eclampsia with the retinal separation as a complication. Theodore M. Shapira.

11

OPTIC NERVE AND TOXIC AMBLYOPIAS

Agatston, S. A. **Congenital cyst of the optic nerve.** Amer. Jour. Ophth., 1944, v. 27, March, pp. 278-279. (2 illustrations, 1 in color, references.)

Anderson, W. A. **Medullated nerve fibers.** Trans. Ophth. Soc. United Kingdom, 1942, v. 62, p. 343.

The fundi of a patient seen in 1943 at the age of 60 years, with normal vision, showed medullated fibers completely covering the edge of each disc. In September and October, 1940, the same patient presented himself with pain on movement of the left eye, reduced vision, optic neuritis, and some macular changes. The vision of the right eye remained normal. After re-

covery there was optic atrophy of the left eye, without light perception, and all of the medullated fibers had disappeared. The medullated fibers of the right eye remained as before.

Beulah Cushman.

Gottlieb, B. **Retrobulbar and peripheral neuritis.** *Rev. Oto-Neuro-Oft.*, 1942, v. 17, Sept., p. 183.

An alcoholic and chronic pipe-smoker exhibited classical symptoms of retrobulbar neuritis and peripheral neuritis of the upper and lower extremities. There was an associated achlorhydria. During treatment the patient was allowed to smoke, but alcohol was limited. He received orally high doses of vitamin-B complex and parenteral vitamin B₁. After five weeks his vision was markedly improved, as was also the peripheral neuritis. Edward Saskin.

King, A. B. **Tunnel vision.** *Quarterly Jour. Studies on Alcohol*, 1943, v. 4, Dec., p. 362.

The term "tunnel vision" has been used to describe an effect of alcohol on the eyes. In the experiments of the author no tendency to blot out the sensitivity of the retina to visual stimuli at the periphery was found in five subjects who ingested 30 to 75 c.c. of absolute alcohol. The author concludes that "tunnel vision" is an inappropriate figure of speech. The reaction time of the eye in accommodating was found to be slowed. Robert N. Shaffer.

McGregor, I. S. **A study of the histopathological changes in the retina and late changes in the visual field in acute methyl alcohol poisoning.** *Brit. Jour. Ophth.*, 1943, v. 27, Dec., pp. 523-543.

The author reviews the literature concerning the ocular and general findings in methyl-alcohol poisoning, then

describes four acute cases. The retina was examined after routine staining with hematoxylin and eosin in bulk. No changes in the retinal ganglion cells could be attributed definitely to the acute poisoning by methyl alcohol, either in the form of lipoid changes in the ganglion cells, in the size and shape of the ganglion cells, or in nuclear content. The optic nerves in each case appeared normal.

Four patients who had been blind in the acute stage were examined a year later. One had no defect of vision, the second a bilateral scotoma, the third an absolute scotoma in one eye while the other eye was normal, and the last a relative scotoma in one eye with good vision in that eye and the other eye normal.

The author concludes that histologic examinations of the retina so soon after poisoning are rare, and that the evidences in acute poisoning are not sufficient to show whether it is the retinal tissue or the nerve tissue which primarily succumbs. The follow-up suggests that the poison acts on the center of the optic nerve. (7 illustrations, references.)

Beulah Cushman.

Mata López and Barthe Pastrana. **A new case of Cruzon's disease.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Oct., pp. 329-335.

The authors report a new case of Cruzon's disease with the typical characteristics of oxycephaly, bilateral exophthalmos, divergent strabismus, diminution of vision, and facial deformities. The pathogenesis of this disease is discussed. In cases accompanied by progressive optic atrophy and diminution of vision, the authors advocate freeing the optic nerve at the optic foramen by the operation of Hildebran,

who has performed it with success in five cases. Ramón Castroviejo.

VISUAL TRACTS AND CENTERS

Evans, J. N., and Browder, J. A problem of split macula. *Arch. of Ophth.*, 1944, v. 31, Jan., pp. 43-53; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41.

The course and function of various fasciculi of the optic pathway have held the interest of ophthalmologists and neuro-anatomists for many generations, because knowledge in this field has a broad application to the diagnosis and treatment of ocular and cerebral disease. There are two general avenues of approach for studies of these fiber bundles. One may produce experimental lesions in various laboratory animals and study the resulting progress of fiber degeneration, or one may make functional studies on human beings who are suffering from certain localized lesions. Functional studies made on human subjects can be supported by anatomic evidence only when the injury or disease is observed at autopsy or operation. A review of the literature disclosed but two instances in which the optic chiasm had been split anteroposteriorly.

The major therapeutic problem that presents itself in attempted removal of a craniopharygioma is minimal injury to the hypothalamic nuclei and their connecting pathways. To this end three methods of surgical approach were utilized: first, removal of the tumor piecemeal, the optic apparatus being left intact; second, section of the one optic nerve in order to obtain a better exposure of that part of the tumor situated beneath the chiasm; third, splitting of the optic chiasm and division of the anterior communicating artery.

The authors report in detail the case of a 13-year-old boy with such a lesion. At operation the chiasm was divided with precision. The fields taken later showed classic bitemporal hemianopsia with a fingerlike absolute central scotoma which protruded from the blind field above the point fixed. The central scotoma could not cover the point fixed, since, macular function being impaired, the paramacular retina was used for this purpose. The true position of the macula was necessarily represented by some point within the fingerlike scotoma.

If the concept that the macular fibers form a semidecussation in the chiasm is adopted, then in the case cited the surgical procedure divided all the crossed macular fibers, with the result that the corresponding part of each macula was rendered functionless. This scotoma may then be assumed to represent the approximate size and shape of the part of the macula supplied by the crossed fibers.

The problem of fixation was of course encountered in the taking of the fields. A great many methods have been suggested for maintenance of fixation, but in this study the authors utilized the principle of the position and size of the normal blind spot and the adjacent angioscotoma. The use of these landmarks insures accurate fixation in normal subjects to within 0.25 degree. The authors conclude that the visual acuity resulting from division of the crossed macular fibers is approximately 20/40, which permits the subject to read and write such material as he is apt to need in average daily life. It is argued that the entire macula must be supplied by both crossed and uncrossed fibers. (References, 5 figures.)

Krug, E. F., and Echlin, F. A. **Tuberous sclerosis.** *Arch. of Ophth.*, 1944, v. 31, Jan., pp. 68-73; also *Trans. Amer. Ophth. Soc.*, 1943, v. 41.

A case of tuberous sclerosis is reported in detail in a young boy who was also afflicted with adenoma sebaceum. The cerebral tumor was removed by surgery with some loss of mental and physical powers. The visual acuity and visual fields were impaired and partial optic atrophy appeared. The term tuberous sclerosis was first used by Bourneville to describe a rare form of cerebral sclerosis occurring chiefly in children and young persons. Vogt, in 1908, established the clinical syndrome of mental deficiency, epilepsy, and adenoma sebaceum. Adenoma sebaceum, or nevus sebaceus, a disease of congenital origin, is characterized by pinhead-sized, yellow or reddish, waxy papules, situated on the flush areas of the face.

Tuberous sclerosis is so named, because of the potato-like appearance of the morbid growth. Neoplasms of this type may appear in the kidney, the heart, the lungs, the spleen, and the retina. Signs of intracranial tension are evident in early adult life, as epileptiform attacks. In the absence of such manifestations, a facial eruption should arrest the attention and suggest the presence of tuberous sclerosis, and concurrent papilledema at once suggests intracranial neoplasm. Associated retinal tumors are comparatively rare. (3 illustrations, references.)

Mello, A. R. de. **Hereditary degeneration.** *Arquivos Brasileiros de Med.*, 1943, v. 33, nos. 3-4 and 7-8, 90 pp. (Received in reprint.)

This ninety-page article reports in detail 16 cases studied in the neurologic clinic of Austregesilo, at Rio de Jan-

eiro. The literature is reviewed. No general conclusions are presented. Most of the patients belonged to familial groups, one family including six affected offspring. Some details of the eye condition are given in most of the cases, the predominating ocular feature being atrophy of the optic nerve, sometimes accompanied by other fundus lesions and sometimes by disturbances of the ocular muscles. (51 illustrations, separate bibliographies of the Brazilian and extra-Brazilian literature.)

EYEBALL AND ORBIT

Abbott, L. D., Mandeville, F. B., and Rein, W. J. **Complete roentgen and ophthalmologic examination for ochronosis in two alcaptonuric children.** *Virginia Med. Monthly*, 1943, v. 70, Dec., p. 615.

Two Negro children, aged 10 and 15

years, with alcaptonuria showed no positive roentgen evidence of joint change, ligament calcification, or calcium deposits in the ear cartilages. Ochronotic pigmentation of the scleras and conjunctivas was not definite, although alterations due to melanosis were found. Because of the racial pigmentation this was viewed as within normal limits but was carefully charted for later study. It is hoped that by follow-up the time of onset of definite changes due to alcaptonuria can be established. One author indicates that evidence of ochronosis may be found in the eyes as early as the third decade of life, although it is usually considered that the ochronosis is due to accumulation of pigment over a period of years and does not develop in alcaptonuria until middle age or later.

Owen C. Dickson.

Dimitry, T. J. The socket after enucleation and the artificial eye. *Arch. of Ophth.*, 1944, v. 31, Jan. pp. 18-28.

The author defines enucleation as the peeling of the eye from Tenon's capsule. He gives a résumé of the various procedures for removal of the eyeball. He insists that random severance of muscles and tissues to rid the orbit of the globe is not enucleation but extirpation. In discussing what happens to the remainder of the contents of the orbit after enucleation, Dimitry states that it is readily demonstrable clinically that improvement does not follow the sewing of opposing rectus muscles but that, on the contrary, disfigurement of the socket is produced. Some men do not even sew the wound, and yet get excellent results.

Various modifications such as implants have been devised in an effort to obtain a mobile stump. Dimitry believes we accomplish the mobile stump

but have been unsuccessful in obtaining the mobile prothesis. He is of the opinion that the plastic prothesis will largely solve the problem of a movable prothesis. He criticizes the ophthalmologist for turning the responsibility of the fitting over to a nonmedical technician. (8 figures, references.)

R. W. Danielson.

Ulluer, L. J. Orbital cellulitis. *Rev. Oto-Neuro-Oft.*, 1942, v. 17, Aug., pp. 143-145.

The author considers orbital cellulitis an acute inflammation of the soft tissues of the orbit, characterized by bulbar congestion, lid edema and ptosis, limitation of ocular motility, chemosis, and a septic fever. He believes that the chief cause of orbital cellulitis is acute nasal-sinus infection (70 to 80 percent of all cases), the pathway being the sinus veins, thence into the superior and inferior ophthalmic veins. Swimmer's sinusitis and the acute exanthemata of childhood are frequent offenders.

Pathologically, orbital cellulitis may result in an orbital phlegmon or abscess, a subperiosteal abscess, or a thrombophlebitis with cavernous-sinus involvement. This latter must be differentiated early from orbital cellulitis. Treatment should be directed toward the infected sinuses (if they exist) drainage of the orbit, and chemotherapy.

EYELIDS AND LACRIMAL APPARATUS

Jiménez González, R. A new operative procedure for senile ectropion. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1942, v. 1, Oct., pp. 339-344.

The method consists in the excision of a triangular piece of tarsus and muscle of the conjunctival aspect of

the lower lid. The base of the triangle is directed toward the fornix. A doubly-armed suture is inserted through the conjunctiva near the lateral incisions close to the base of the triangle, and the two ends of the doubly-armed suture, threaded on one needle, are then passed through the conjunctiva below the base of the triangle and brought out on the skin at about the center of the lower orbital margin. The threads are tied in this position, pulling them to the extent necessary to correct the ectropion. In subsequent dressings the position of the lid may be controlled by loosening or tightening the suture. (5 illustrations.)

Ramón Castroviejo.

Lemere, H. B. A vacuum device for the eyelids. *Arch. of Ophth.*, 1944, v. 31, Jan., p. 95.

Expression of the meibomian glands by digital pressure or by some form of spatula, while not very painful, is occasionally objected to by the patient. In a situation of this kind, the author attached the glass portion of a medicine dropper to the tubing of the suction apparatus used for nasal displacement treatment. He found that passage of the end of the dropper back and forth along the margin of the lids tended to evacuate accumulated material from both the meibomian glands and the hair follicles.

He has found this procedure a valuable adjuvant to treatment in practically all his cases of chronic and in some cases of acute conjunctivitis. He instills a drop of 0.5-percent solution of pontocaine hydrochloride a minute before using the suction, and two drops of a 1 to 500 solution of silver nitrate afterward to take care of any floating material resulting from the suction.

TUMORS

Black, G. W. Melanotic sarcoma of the iris. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 304-306.

Sarcoma of the iris furnishes 2 to 6 percent of the malignant tumors of the uveal tract. The author reports a case in a woman 64 years of age. A brown patch on the left iris which had been noticed for 40 years became slightly larger, with flattening of the pupillary margin. The mass was removed by iridectomy through a keratome incision and covered by a conjunctival flap. The pathologic report showed an early spindle-cell type of melanotic sarcoma, the peripheral portion intensely pigmented, corresponding to the brown patch. At the pupillary margin the tumor mass was highly cellular and contained scanty pigment.

Beulah Cushman.

Black, G. W. Reticulum-cell sarcoma. *Trans. Ophth. Soc. United Kingdom*, 1942, v. 62, pp. 316-317.

A plum-colored tumor attached to the outer surface of the external rectus

muscle by fibrous trabeculae was removed. On microscopic examination the bulk of the tumor consisted of large closely packed cells with rounded or oval vesicular nuclei and ill-defined cytoplasm as of reticulum cells. The arrangement was diffuse, with a fair number of mitotic figures. There was moderate infiltration by lymphocytes but no lymph follicles.

Burch, F. E., and Camp, W. E. **Results of irradiation of malignant melanomas of the uveal tract.** *Trans. Amer. Acad. Ophth. and Otolaryng.*, 1943, 47th mtg., May-June, pp. 335-352.

Even intensive irradiation of the eye is valueless in any of the types of malignant melanoma. Roentgen therapy does not assure against metastasis; there is even a possibility that metastases develop earlier after irradiation than when it is not employed. Irradiation should be reserved for cases in which only the tumor-containing eye retains vision, for cases in which the patient refuses enucleation, and those in which the orbit and adjacent structures are already invaded. INJURIES

Allen, T. D. **Industrial ophthalmology.** *Surg. Clinics North America*, 1942, v. 22, Aug., pp. 1011-1028. (See Section 18, Hygiene, sociology, education, and history.)

Berens, C., and McAlpine, P. T. **Solar keratoconjunctivitis associated**

with amblyopia. *Amer. Jour. Ophth.*, 1944, v. 27, March, pp. 227-231. (6 fields, references.)

Dickson, R. M. **First-aid treatment of industrial eye injuries.** *Brit. Jour. Ophth.*, 1943, v. 27, Dec., pp. 544-548.

The author records the results after six months trial of the use of 10-percent sodium-sulphacetamide solution as first-aid treatment in eye injuries in 30 mines and 30 factories. Of the total injuries in 30 mines in Scotland, 96 percent returned to work with no loss of working time. In the shipyards 98.87 percent of the patients lost no working time. (References.)

Beulah Cushman.

Gundersen, T., and Liebman, S. D. **Effect of local anesthetics on regeneration of corneal epithelium.** *Arch. of Ophth.*, 1944, v. 31, Jan., pp. 29-33.

Clinically it has been observed from time to time that local anesthetics have an inhibitory influence on the regeneration of corneal epithelium. In this investigation, the corneas of guinea pigs were abraded and measurements were made of length of time required for regeneration of the corneal epithelium when various anesthetics were used hourly during healing. The drugs used were solutions of 10-percent cocaine hydrochloride, 4-percent cocaine hydrochloride, 1-percent butacaine sulfate, 4-percent larocaine hydrochloride, 1-percent phenacaine hydrochloride, and 0.5-percent tetracaine hydrochloride. All solutions contained 0.5-percent chlorobutanol.

Both 10- and 4-percent cocaine very definitely retarded the regeneration of epithelium; more retardation was observed with the stronger solution. In fact, repeated instillations on the intact epithelium produced corneal areas

which stained with fluorescein. The inhibitory effect of cocaine diminished as increasingly hypertonic solutions were used. Tetracaine gave similar results, although less pronounced. The delayed healing of the epithelium was observed in varying degrees with 1-percent phenacaine, 1-percent butacaine sulfate, and 4-percent larocaine. One percent phenacaine and 0.5-percent tetracaine were the least toxic. The pH is probably not a determining factor, since buffered solutions at a pH comparable to that of the anesthetics used showed relatively little inhibitory action. Two very descriptive charts are included. (References.)

Jaime, G. G. **Cephalic tetanus of ocular origin.** Rev. Oto-Neuro-Oft., 1942, v. 17, Jan.-Feb., pp. 22-26; March-April, pp. 52-58; May-June, pp. 88-94.

Cephalic tetanus, or tetanus limited to the region of the head, follows facial injury (orbit, nose, temporal, or malar regions). There is an incubation period of at least one week, after which the typical unilateral or bilateral trismus occurs, followed later by facial paralysis. This paralysis is of the peripheral type, and the muscles involved need

not be near the site of injury. Occasionally, the above symptoms are preceded by an ophthalmoplegia manifested by ptosis. Other eye signs noted are miosis and fixed pupils. The author cites several cases of cephalic tetanus following ocular injury, such as perforation of the cornea associated with loss of the eye. The affection is relatively rare. Etiologically, the offending organism is Nicolaier's bacillus, *Clostridium tetani*, found in the infected wound in or around the lids, orbit, or the eyeball. The author claims conclusive proof that the organism is Nicolaier's bacillus, and that there is an associated virulent toxin. He offers a mechanical theory of the pathogenesis by which the toxin causes a direct nerve irritation. A reflex theory of the pathogenesis involves the trigeminus as the conducting pathway of the toxin, which latter affects the facial nerve and the third, fourth, or sixth nerves. A third, directly infectious theory claims a toxic or bacterial invasion of the body fluids from the infected wound. The author states that whatever theory is finally accepted the passage of the organism or toxin is centripetal, backward from the wound.

The author discusses his studies of diagnosis, course, prognosis, symptomatic and specific treatment, active and passive immunization, preventive serotherapy, therapeutic serotherapy, and anaphylaxis. The diagnosis is simple, given an infected wound about or of the eye, an incubation period, then facial trismus or paralysis. The course may be acute, subacute, or chronic, lasting as little as two days and ending in death, or becoming protracted with a more satisfactory outcome. The prognosis is usually guarded, even in the protracted cases. There may be residual paralysis or paresis if death does

not intervene. The treatment is symptomatic, as in generalized tetanus. Specific antitoxin is administered in addition. The author's active immunization is similar to our vaccination with an attenuated toxin; passive immunization is specific. He also discusses using blood serum from well individuals previously stricken, as well as intravenous, intra-arterial, and intracranial administration of the antitoxin, always being on the watch for hypersensitivity.

Edward Saskin.

Kirby, D. B., and Town, A. E. *Injuries of the eyes and eyelids*. Surg. Clinics North America, 1943, v. 23, April, pp. 404-438.

The authors present a comprehensive discussion and review of the prevention, diagnosis, and treatment of ocular injuries of all kinds. The usual treatment of traumatic lesions and burns is covered, as well as later surgical treatment—plastic surgery—to remedy defects. (10 illustrations, references.)

R. C. Richardson.

Mann, Ida. *A study of epithelial regeneration in the living eye*. Brit. Jour. Ophth., 1944, v. 28, Jan., pp. 26-39.

Experimental study of epithelial regeneration in the eyes of rabbits showed formation of pigment in the basal cells of the conjunctival or corneal epithelium. The pigment allowed recognition of the particular cells involved, and their migration could be followed from day to day with the loupe or slitlamp. The initial loss of epithelium was confirmed by the use of fluoresceine, and the observations originally made on rabbits were confirmed clinically in man. The injuries were produced by scraping, chemicals and heat, without damage to the underlying tissues.

The first series of experiments demonstrated the movement of the pigmented epithelium in an irregular line which met the slide of epithelium from the opposite side in less than 20 hours. The pigment from these advanced cells gradually disappeared as the cells were replaced, and the original pigment line, which had become thinner, gradually assumed its original density. The area of spread from the activating substance seemed to be more than 2.5 mm. and less than 5 mm. from the edges of the wound in all directions. If the injury was produced by a hot wire the movement of the pigment epithelium was much less, was very irregular, and did not occur all around the burned area, the heat having evidently destroyed the activating substance. If the conjunctiva was injured near the cornea, the pigmented cells slid toward the area as though the wound were in the cornea.

A second series of experiments involved injury to larger areas of the cornea by various chemicals. Healing of the superficial loss was usually complete within four days, whereas the pathologic process continued its course beneath the epithelium for days or weeks. If the whole width of the ring had migrated, the gap in the limbal pigment never completely regenerated.

A third series of experiments dealt with production of pigment proliferation in response to chemical injury by the arsenical war gases. In this type of injury the proliferation did not occur until after healing of the epithelium, but it was progressive and continued to increase for months.

A fourth series of experiments dealt with pigment migration in vitamin-A deficiency. It could be produced experimentally in rabbits without epithelial loss, and was based upon a wandering of chromatophores.

The experiments corroborate the general agreement that epithelium heals by migration from the edge of the denuded area, associated with mitosis at some distance from the defect. Thus the loss is made good by pre-existent cells which move actively across to cover the raw zone, and these cells are replaced by cell division behind their original positions and not over the wound area. (14 illustrations, references.)
Beulah Cushman.

Moore, P. G. **Management of magnetic foreign bodies in the eye.** Ohio State Med. Jour., 1944, v. 40, Jan., p. 26.

An adequate headrest, oblique illumination, a loupe with a half-inch focal distance, and a sharp Graefe knife are stressed by the author as necessary for proper removal of corneal foreign bodies. Distinction between the dead white ring of coagulated tissue surrounding a hot foreign body and the gray of an infected infiltrate is important. The author uses a 1 to 500 zinc sulphate solution as routine antiseptic. He feels that bandaging of eyes following removal of obviously uninfected foreign bodies is not indicated if the corneal surface is not denuded. Infection, shown by the appearance of a gray ring on the second day, requires wiping out the wound with a stronger antiseptic such as 3.5-percent iodine or trichloroacetic acid.

Management, indications for anterior or posterior approach, and postoperative care of patients with intraocular magnetic foreign bodies are also discussed. Indications for enucleation are enumerated, with the emphasis on conservatism unless the eye is unquestionably blind and irritable or painful.

Owen C. Dickson.

Pierse, Dermot. **A case of removal of nonmagnetic foreign body from the ciliary region.** Brit. Jour. Ophth., 1943, v. 27, Dec., pp. 550-552.

In a man 38 years of age a small piece of brass perforated the cornea and was visible in the angle of the anterior chamber. The vision was 6/9, the lens clear, and no abnormality was seen in the fundus. There was no response to the giant magnet, and the fragment disappeared backward upon the attempt to grasp it through a corneal incision. It was then localized accurately on an X-ray film with the aid of a needle inserted in the sclera. The approach was made 4.0 mm. from the limbus, using a hinged flap of sclera. The ciliary body was investigated with the point of the knife until the foreign body was felt, when it was easily removed through the ciliary body. The scleral flap was closed with a previously inserted suture, and the conjunctiva replaced. Two weeks later the vision with -0.75 cyl. axis 175° was 6/6. (References.)

Rosen, Emanuel. **An interesting case of rupture of the choroid.** Brit. Jour. Ophth., 1943, v. 27, Dec., pp. 552-554.

The author reports two cases with rupture of the choroid in the macular area, one with resulting corrected vision of 20/20 and the other of 8/200. He concludes that the distinct anatomy of the macula modifies the traumatic pathology. (2 illustrations.)

Beulah Cushman.

SYSTEMIC DISEASES AND PARASITES

Carmichael, F. A. **Migraine, a review.** Jour. Kansas Med. Soc., 1943, v. 44, Oct., p. 333.

The basic mechanisms mentioned are: pressure on cranial and upper cervical nerves, traction on or spasm of the basilar vessels, traction or reduced caliber of venous sinuses, and inflammation in or about pain-sensitive structures. Causation involves many apparently unconnected details which, however, can be resolved into three fundamental elements combined in varying proportions. The first is the hereditary factor, which is known to exist in 70 percent of migraine sufferers and which includes a predisposition to this syndrome in some parts of the brain and of the autonomic nervous mechanism. The chemical details of these changes are not yet known, but those afflicted frequently also have other neuroses especially involving the vasomotor mechanism. The second factor is that of age, 80 percent of migraine beginning between the ages of eight and ten years, somewhat before puberty. Most women sufferers are relieved by the menopause, and in some the attacks are influenced by menstruation. The third or environmental factor includes physical and chemical conditions of many kinds which intensify or retard the hereditary predisposition, thus altering the minimal time between attacks as well as their severity. Among those mentioned are histamine sensitiveness, the environmental factors which aggravate hypertension, compression of the fifth nerve, and a small calcarine tumor whose removal was curative. Migraine, however, is apparently less frequent in patients with

liver or biliary tract disease, the reason being as yet unknown.

In the treatment two drugs are emphasized: ergotamine tartrate, a vasoconstrictor, and potassium thiocyanate, a vasodilator. The former should not be used in patients with anginal symptoms and other evidence of obliterative vascular disease. The latter is apparently better adapted for migraine sufferers with hypertension.

Michaelson, I. C. **Ocular manifestations of neuroses found among soldiers.** Brit. Med. Jour., 1943, Oct. 30, p. 538.

This report deals with the ocular manifestations of hysteria and of the

chronic anxiety state, these being the two most common neuroses. In hysteria, the most common symptoms are diplopia and defective day or night vision.

Of the anxiety states, asthenopia, headache, photophobia, muscae volitantes, and epiphora are more common. The authors point out the importance of evaluating functional and organic components in each case. In any of the more severe cases the help of a psychiatrist is needed to effect the profound personality change necessary for permanent removal of the underlying cause of the patient's symptoms.

Robert N. Shaffer.

Murphy, R. C., Jr. An eruptive fever involving the mouth and eyes (Stevens-Johnson disease). *New England Jour. Med.*, 1944, v. 230, Jan. 20, p. 69.

About twenty cases characterized by acute and at times fulminating systemic reactions with fever, prostration, generalized skin rash, and severe stomatitis followed by sloughing with eventual recovery have been reported. A mucopurulent type of conjunctivitis is noted almost constantly. No etiologic agent has been discovered. Panophthalmitis has occurred with loss of the eyes in several patients. This may be due to secondary conjunctival invasion by staphylococcus aureus as suggested by recovery of this organism in the present reported case. Previously reported cases ran from 22 months to 16 years, the great majority being in males.

The present case is that of a 22-year-old Italian male. At onset the disease appeared as a tenderness of the buccal mucosa, with rapid appearance of tight whitish vesicles surrounded by erythema, which proceeded to rupture and slough. Temperature between the third

and sixth days varied around 104.6 F. No vesicles appeared on the conjunctivas, although they were diffusely inflamed and a mucopurulent discharge was present. The temperature fell on the eighth day. Similar lesions (vesicles) appeared on the extremities and on the glans penis and corona. Crusting of the lesions had occurred by the seventeenth day, and before the end of the fourth week the scars were barely visible.

This is thought to be a definite clinical entity, although etiologic relation to Vincent's stomatitis is not confirmed. The description used for these cases has been "erythema multiforme bullosum with involvement of the mucous membrane of the eyes and mouth."

Owen C. Dickson.

Negus, V. E. The relationship of ophthalmology and rhinology. *Brit. Jour. Ophth.*, 1943, v. 27, Dec., pp. 554-557.

The author urges that in many conditions about the nose and eyes the rhinologist and ophthalmologist should work together. He suggests that the label "orbital cellulitis" is often misleading, these being really cases of frontal sinusitis and acute ethmoiditis with orbital edema. They should be treated with lavage of the maxillary sinus, which is usually infected, and with an ephedrine spray.

The author has seldom found iridocyclitis due to suppuration of the nasal sinuses, although infected tonsils were often causative factors. Desensitization and medical treatment of nasal allergy often improved a concurrent conjunctivitis.

Beulah Cushman.

Thygeson, Phillips. Virus diseases of the eye. *Trans. Pacific Coast Oto-Ophth. Soc.*, 1942, v. 27, pp. 58-102.

The material covered by this article is very similar, although somewhat more briefly stated, to that published in the Archives of Ophthalmology, 1943, v. 29, Feb., p. 285; March, p. 488; and April, p. 635. (See abstracts, Amer. Jour. Ophth., 1943, v. 26, June, p. 666; and Aug., p. 892.)

Woods, A. C. Syphilis of the eye. Amer. Jour. Syph., Gonorrhea, and Ven. Dis., 1943, v. 27, March, p. 133.

This long and valuable survey of the subject includes consideration of the various stages of congenital and acquired syphilis respectively, with a statement of the lesions which prevail in each period of either form of the disease. Consideration is given to the type of treatment suitable for each combination. Particularly valuable sections are those dealing with neuro-ocular lesions of late meningovascular neurosyphilis, and with degenerative neurologic lesions. Three basic types of optic-nerve atrophy are discussed, with the corresponding visual fields. Type one, representing 12 percent of these cases, progresses from the periphery into the center, and has concentric visual fields and late loss of vision. Type two (34 percent of the cases) progresses from the pia in the form of a wedge, involves sectors of the optic nerve, and has sector-shaped fields and either early or late loss of vision. Type three (54 percent of the cases) progresses as a generalized degeneration, and has cecocentral scotomas, either with or without peripheral field defects, and with early loss of vision. We are reminded that vitamin-A and B deficiencies may be contributory or aggravating factors. Subdural treatment with arsphenaminized serum is said to reduce blindness to 50 per-

cent at the end of nine years but is occasionally responsible for sudden extinction of what vision is present. For malaria and other forms of fever therapy it is claimed that only 14 percent of the patients are blind at the end of nine years. Charles A. Bahn.

Yudkin, A. M. Nutrition as it affects the eye. Med. Clinics of North Amer., 1943, v. 27, March, pp. 553-560.

Brief consideration is given to ocular disturbances on a background of nutritional deficiency, with special mention of night blindness, conjunctivitis and blepharitis, chorioretinitis, and vitamin therapy. The author also discusses secondary ophthalmic disorders which are regarded as sometimes responding to treatment with vitamins, such disorders including marginal ulcers of the cornea, early stages of cataract, hemorrhagic retinitis, and toxic amblyopia from alcohol and tobacco. HYGIENE, SOCIOLOGY, EDUCATION, AND HISTORY

Allen, T. D. Industrial ophthalmology. Surg. Clinics North America, 1942, v. 22, Aug., pp. 1011-1028.

Allen discusses industrial ophthalmology from the standpoint of the general surgeon, rather than from the standpoint of the ophthalmologist. The importance of preemployment and periodic eye examination is considered, as well as that of good lighting in industry. There is mention of the treatment of minor eye injuries, as well as of the treatment of more serious injuries such as retinal detachment, intraocular foreign body, and ocular burns. (7 illustrations.) R. C. Richardson.

Beach, S. J. The American Board of Ophthalmology learns about written examinations. *Med. Clinics of North America*, 1943, pp. 1409-1415. (See *Amer. Jour. Ophth.*, 1943, v. 26, Sept., p. 911.)

Birren, F. Color technique in industry. *Sight-Saving Review*, 1943, v. 13, May, p. 3.

Selection of colors in industry must be directed at minimizing work hazards and ocular fatigue. Rest rooms, lunch rooms, and so on, should feature soft, cheerful colors—as blue and rose. In work rooms, ceilings and upper walls should be white or bright blue; floors, a light color reflecting about 25 percent; and lower walls and machinery, a soft gray color reflecting 25 to 40 percent—thus giving the fixated part of the field the same illumination as the adjacent parts.

In general, yellow (not red) should be used for critical hazards; yellow-green or orange for lesser hazards; and red reserved for fire escapes, exits, and the like.

Benjamin Milder.

An eye health program for schools. *Sight-Saving Review*, 1943, v. 13, May, p. 22.

The minimum recommended intensity of illumination for close work at school should be 15 foot-candles, in diffuse, glare-free illumination. Natural illumination should be provided through windows occupying space at least equivalent to 16 percent of the area of the floor, situated to the left of the pupils. Walls should be of light color, with dull finish. Seating should be so arranged that the desks are turned at a 30° angle away from the windows. (The authors do not seem to give any attention to the question of

the teacher's position in relation to the light, or of reflections from the black-board.) Printed matter should be 10-point for children over twelve years old, increasing to 24-point or 30-point for children under seven years.

Education of teachers is important in an eye health program, with emphasis on special attention to those children requiring it. The testing of visual function must be undertaken in school. Cooperation between parents, school, and medical profession will produce the best results. Education of child, parents, and the community is the final, all-important objective of an eye health program for schools.

Benjamin Milder.

Gruber, K. F. The vocational training program for the visually handicapped in the Minneapolis public schools. *Sight-Saving Review*, 1943, v. 13, no. 2, p. 104.

Before the establishment of a vocational-training program the visually handicapped were graduated from the Minneapolis public schools with purely academic skills. The present plan permits 12th-grade students in the sight-saving classes to spend part of their time in selected industries earning credits to be applied toward graduation.

Careful studies of aptitude of individual pupils are made through cooperation of an ophthalmologist, a psychologist, and the school, including a coöordinator between school and industry. The family background is studied; intelligence and aptitude tests are given; recommendations are made. The student chooses the training plan which interests him most.

In the industry the pupils are carefully supervised. Every effort is made to make them compete on even terms

with nonhandicapped workers. In the school, effort is made to coach the pupils in qualities, such as punctuality, courtesy, independence, and personal appearance, which will aid them in obtaining employment.

Robert N. Shaffer.

Kuhn, H. S. **Significance of visual defects in war production effort.** Jour. Amer. Med. Assoc., 1943, v. 123, Dec. 25, p. 1085.

The consulting ophthalmologist working with industries must supervise with extreme vigilance the entire industrial program; treatment of eye injuries, eye-protection plans, job standard evaluations, and rehabilitation procedures. Physicians should not hesitate to offer their services to industries. (One figure, 2 tables, discussion.)

George H. Stine.

Landa Lion, Luiz. **Ophthalmology of high altitude.** Arquivos Brasileiros de Oft., 1943, v. 6, Aug., pp. 141-143.

A special ophthalmology of high altitude exists by reason of the special meteorological, climatic, and racial conditions. The author finds in the South American altiplano a people with special characteristics, religious, artistic, and physical. These people have large thorax and slight development of the lower extremities. Their physiologic attributes include hypotension and polyglobulia. A semianesthetic condition of the tissues arises from the chewing of coca by 70 percent of the population. Glaucoma is rare, and the author speaks of this fact as supporting the interpretation of that disease as a local manifestation of a general condition. Pterygium is frequent in Bolivia as compared with other countries, and is interpreted by the writer as a mechanism of defence against the constant ac-

tion of the winds occurring in that region. In La Paz trachoma is unknown, and the trachoma patients of Argentina visit that city for relief from their disease. It is said that, on account of the chewing of coca, the Bolivian ophthalmologist, when operating upon the eye, does not have to concern himself greatly with the question of anesthesia.

W. H. Crisp.

Lester, Eileen. **Opportunities for the visually handicapped through job analysis.** Sight-saving Review, 1943, v. 13, May, p. 29.

The visually handicapped may fall in this category by virtue of low corrected visual acuity, impairment of visual field, progressive ocular disease, various degrees of color blindness, muscular imbalance, or impairment of stereopsis.

Industrial surveys indicate that the vast majority of large concerns make no effort at job analysis in regard to visual requirements; a majority make an inadequate visual test, or none at all; and very few have any program for conservation of sight.

It is essential to undertake thorough job analysis to determine what jobs can be performed by persons with visual limitations. It is equally important to provide a full and adequate program of examination of all job applicants, including the visually handicapped, with an estimate of how the individual can best use whatever visual abilities he has.

Benjamin Milder.

Mann, Ida. **The scope of prevention in ophthalmology.** Brit. Med. Jour., 1943, Oct. 16, p. 482.

The existence in England and Wales of 74,000 blind persons whose support costs the state 4½ million pounds yearly emphasizes the importance of planned prevention of blindness. Re-

duction of the incidence of eye diseases could come from three ways: (1) Improving the services of the oculist, by making modern ophthalmic-hospital treatment available to everyone, by standardizing the system of training ophthalmologists and requiring a uniform standard of examination, by close supervision and better facilities for diagnosis and treatment of children under school age and of adolescents leaving school. (2) Educating the public. Some biologic and physiologic instruction in schools should be obligatory, including the mechanism of sight, the errors of refraction, and presbyopia. The industrial worker should be instructed in methods of protecting the eyes. (3) Establishment of research teams (in association with laboratories) in which physicists, biochemists, physiologists, and pathologists among others could unite with ophthalmologists for solving given problems.

R. Grunfeld.

Martin, H. G. **Fads and fallacies regarding our eyes.** *Milwaukee Med. Times*, 1943, v. 16, Nov., pp. 15-19.

As 80 percent of our intellectual development is acquired through visual processes, and as our eyes were not intended by nature to be used as we use them, the symptoms of ocular discomfort are frequent. The author does not, however, discuss in detail just how to avoid the misuse of the eyes. Ocular conditions stand first or second on all lists as causes of rejection for the armed forces. Clear sight develops at the end of the first year and binocular vision about the fourth year. The author believes that faulty ocular habits during this time produce symptoms later in life, and that many children's eyes are not given a chance to develop normally. Such exercises to strengthen

the eyes as are now in vogue have had periods of favor during the past hundred years, Rolling the eyes in different directions, as popularly practiced, exercises strong and weak muscles equally, and therefore can accomplish no good.

Charles A. Bahn.

Morgan, D. H. **Vocational aptitudes of the visually handicapped.** *Outlook for the Blind*, 1943, May, p. 125.

Advanced vocational training for the blind and partially blind is discussed. Examples of successful candidates from the California School for the Blind for placement in the shops of the public high schools are described. A program for handling the visually handicapped is offered, with special suggestions on how to overcome the discouraging attitude of principals of public high schools.

Francis M. Crage.

Prado, Durval. **Contribution to the history of optics in São Paulo.** *Arquivos Brasileiros de Oft.*, 1943, v. 6, Aug., pp. 124-127.

The history of optics in São Paulo, Brazil, dates back about a half century. The first of three phases was purely commercial. Most of the glasses were of French origin and took the form of pince-nez. At that time, only sufferers from external disorders of the eyes made free use of smoked or blue glasses. The choice of glasses depended entirely at best upon a short reading at the time of purchase, the person's age serving as the main criterion for determining the proper "number." Systematic borrowing of glasses among the less fortunate was frequent. The glasses were graded by numbers in inches. They were sold at stores for surgical supplies, musical articles, clocks, and so on.

The first attempt at an optical work-

shop appeared about 1895, the grinding being done on a stone wheel moved by a pedal managed by the operator. Up to that time São Paulo had not possessed physician oculists properly so called. The few prescriptions which appeared had to do with presbyopia or simple myopia.

Beginning with 1902 the scientific phase of optics in São Paulo appeared with the settlement there of a number of physician oculists, foreign and Brazilian, almost all of whom had had special courses in Europe. Up to 1912 prescriptions for myopia predominated, although Pignatari began in 1902 the prescription of cylindrical lenses and the notation in diopters. The cylinders were usually prescribed at horizontal or vertical axes. But some prescriptions showed axes between 30 and 60 degrees. Beginning with 1912, the newly founded School of Medicine and Surgery in São Paulo taught ophthalmology as a true specialty. The laws of Brazil have not yet recognized a profession of optometry. W. H. Crisp.

Suheyil Unver. Remarks concerning the history of Turkish ophthalmology. *Göz Klinigi*, 1943, v. 1, Aug., p. 16.

In the Orient ophthalmology was practiced as a specialty for many centuries, especially in Turkey. The ophthalmologist was called "Kehhal," which is Arabic and originally meant "cosmetic for the eye." Reference is made to many old textbooks and monographs about eye diseases, generally written in the Arabic language, but some of them in Turkish. The most famous authors were Ali Ibni Isa Elmedujisi (ninth century) and Ibni Sina (Avicenna, 980-1037 A.D.). Centuries ago an eye doctor was attached to each hospital. J. Igersheimer.

Vaughan, M. S. Public health nursing in a trachoma control program. *Sight-Saving Review*, 1943, v. 13, no. 2, p. 91.

The author summarizes the methods and difficulties of establishing a trachoma-control clinic in Arkansas, organizational structure and efforts to educate both personnel and public being outlined. She sums up her article by saying that "the public-health nurse's services in a trachoma-control program are essentially the same as in any other public-health program for control of communicable disease."

Robert N. Shaffer.

Weiss, Charles. The geographical distribution of ocular infections. *Amer. Jour. Ophth.*, 1944, v. 27, Feb., pp. 175-177. (One table, references.)

19

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Stone, L. S. Return of vision in transplanted adult salamander eyes after several days of refrigeration. *Proc. Soc. Exper. Biol. and Med.*, 1943, v. 34, Oct., p. 44. (See Section 13, Eyeball and orbit.)

Stone, L. S., and Dinnean, F. L. Lens induction in the salamander (*amblyostoma punctatum*) with special reference to conditions in experimentally produced cyclopia. *Yale Jour. Biol. and Med.*, 1943, v. 16, Oct., p. 31.

In a series of experiments the authors show that the lens in *amblyostoma punctatum* arises in the surface ectoderm by induction of the eye-forming center at a definitely circumscribed period in its development. If this center is absent, no lens is produced. Defects

produced in the prechordal substrate by immersion in lithium-chloride solution or by surgical means gave rise to cyclopia and other malformation. This

emphasizes that conditions in the lens are always subservient to the dominance of the eye-forming centers.

PAN-AMERICAN NOTES

Edited by DR. M. URIBE TRONCOSO
500 West End Avenue, New York 24

Communications should reach the Editor by the twelfth of the month

MISCELLANEOUS

Argentina. Under the direction of Prof. Baudilio Courtis the Section of Ophthalmology of the "Patronato Nacional de Ciegos" has been entirely reorganized. This institution for the blind opened, one year ago, a modern dispensary called "Consultorio Central—'Pedro Lagleyze'" in honor of Professor Lagleyze, one of the most famous oculists of Buenos Aires. The building of the Patronato was erected by private contributions amounting to \$150,000. It is a large structure of modern architecture, has four floors, and is provided with complete appliances for the diagnosis and treatment of eye diseases.

Brazil. In July of 1943, a decree was signed instituting the compulsory use of Crêde's method in the State of Bahia.

JOURNALS

Anales de la Sociedad Mexicana de Oftalmologia y Oto-Rino-Laringologia. This journal contains the following articles dealing with ophthalmologic subjects: July and August, 1942, Dr. José Saenz Canales: "Cystic formations in the vitreous, a clinical case"; September-October, 1942, Dr. M. de Rivas Cherif: "Bio-photo-micrography of the eye—A preliminary note"; November and December, 1942, Dr. Paul A. Chavira: "Treatment of penetrating injuries of the anterior segment of the eye"; May-August, 1943, Dr. Paul Gonzáles Enríquez: "Optochiasmatic meningitis," with a commentary by Dr. Manuel Marquez; and September-December, 1943, Dr. Robert Fitzpatrick: "Mydriasis and the different drugs to produce it."

SOCIETIES

Argentina. At the third monthly meeting, held in May, 1943, The Argentinian Ophthalmological Society awarded its annual prize for "the best paper read" to Drs. Flaminio Vidal and Jorge Malbran for their essay on "Disposition of myelin fibers in the chiasma of a cat." (Experimental study.)

The Ophthalmological Society of the Litoral

in Rosario, Argentina, elected the following officers to serve during 1942-1944: President, Prof. Carlos Weskamp; General Secretary, Prof. Adj. Dr. Juan Manuel Vila Ortiz; Treasurer, Prof. Adj. Dr. Roberto E. Giqueaus; Members: Prof. Adj. Dr. Isaac Cottlier, Dr. Luis A. Gallo, Dr. Salvador Imbern, and Dr. Juan Maggi Zavalia.

II Pan-American Congress of Ophthalmology. The Uruguayan Committee in charge of the organization of the Congress, taking into account the world situation, feels that the meeting should be postponed until November 3, 1944. The scientific program remains unchanged, one day being given to each of the following four sections; as follows:

Social Ophthalmology: Official papers prepared by the Committees on Prevention of Blindness and Trachoma of the Pan-American Congress of Ophthalmology.

Research Papers—Medical Ophthalmology: Four papers on glaucoma have been chosen for this section as follows: "The pre-glaucomatous state—Its diagnosis and treatment." "New ideas on glaucoma derived from gonioscopy." "Estimation and mechanism of the destructive effects of ocular hypertension." "Surgical intervention in glaucoma—How far can medical treatment be continued?"

Surgical Ophthalmology: "Surgical treatment of paralytic strabismus." "Surgical treatment of heterophorias." "Surgical treatment of heterotropias."

Free Papers.

Chile: The Chilean Committee of the Pan-American Congress of Ophthalmology has elected the following officers: President, Prof. Carlos Charlin; Vice-Presidents, Prof. C. Espildora Luque, Prof. I. Martini, and Dr. S. Barrenechea who is the Chilean Delegate to the Council of the Congress; Treasurer, Dr. Ida Thierry; Secretary, Prof. J. Vardaguer; Members of the Committee, Drs. A. Schweitzer, R. Costa, and R. Contardo. Dr. J. Thierry is the president of the Valparaíso Committee and the members of this committee are Drs. Tuyll Kuhlman, and A. Robert. The Chilean Com-

mittee has already sent a list of subscribers to the Pan-American Congress of Ophthalmology to the executive secretary, Dr. Conrad Berens.

A new society of the Fellows of the Kellogg Foundation—Pan-American Congress of Ophthalmology. On October 13, 1943, at a meeting in Chicago at which were present Drs. Bertha R. Noble, Daniel Silva, and Eduardo Barduño, from Mexico; Manoel da Silva from Brazil; Carlos H. Candray from El Salvador; Juan A. Diaz, from the Dominican Republic; Gustavo Vasquez from Paraguay and Augustin Peret from Venezuela, Fellows of the Kellogg Foundation Pan-American Congress of Ophthalmology, it was decided to found a Society which will promote a greater understanding between the Kellogg Fellows and develop cultural and social exchange between the ophthalmologists of the Americas. Dr. Harry S. Gradle was nominated honorary president in recognition of his work in Pan-American ophthalmology. A committee composed of Drs. Daniel Silva, Augustin Peret, and Manoel da Silva was elected to organize the Society and to draw up the statutes.

PERSONALS

At an extraordinary public meeting on July 29th, Dr. Romulo Gil was received as a member of the Argentine National Academy of Medicine. Dr. Gil will take the place of Dr. Noceti, deceased.

The Moura Brasil Prize for 1943 was won by Dr. Sylvio de Abreu Fialho of Rio de Janeiro, with a paper on "Contribution to the problem of the diagnosis of early glaucoma."

The following is a list of the doctors who are already in the United States studying at selected clinics as beneficiaries of the Kellogg Foundation—Pan-American Congress of Ophthalmology Fellowships: *Brazil*: Dr. Manoel Antonio da Silva of São Paulo, at the Illinois Eye and Ear Infirmary, Chicago; Dr. Heitor da Costa Pinto Marbach of Bahia, at The Johns Hopkins Hospital, Baltimore; Dr. Geraldo Queiroga of Minas Geraes, at the University of Iowa, Iowa City. *Chile*: Dr. Michel Mehech Haddad of Santiago at the Mayo Clinic, Rochester, Minnesota. *Costa Rica*: Dr. Alvaro Montero Padilla of San José at Cook County Hospital, Chicago. *The Dominican Republic*: Dr. Juan Antonio Diaz Espinal, of Ciudad Trujillo, at Wills Hospital, Philadelphia. *El Salvador*: Dr. Carlos Candray of San Vicente, at the Massachusetts Eye and Ear Infirmary, Boston. *Haiti*: Dr. Joseph Roger Malebranche of Cap-Haitien, at New York University, New York City. *Honduras*: Dr. Efraín Ochos Reina

of Comayagua, at the Memphis Eye, Ear, Nose and Throat Hospital, Memphis, *Mexico*: Dr. Eduardo Garduño Ballesteros of Villa Obregón, at the New York Eye and Ear Infirmary, New York City; Dr. Daniel Silva Lopez Hermosa of Mexico City, at Northwestern University, Chicago; Dr. Bertha Riveroll Noble of Mexico City, at Tulane University, New Orleans. *Paraguay*: Dr. Gustavo Adolfo Vasquez of Asunción, at Columbia University, New York City. *Peru*: Dr. Enrique Samuel Haro of Lima, at the Stanford Lane Hospital, San Francisco. *Puerto Rico*: Dr. Mariano Cecil Caballero of San Juan, at the New York Eye and Ear Infirmary, New York City. *Venezuela*: Dr. Agustín Perret-Gentil of Caracas, at the Illinois Eye and Ear Infirmary, Chicago.

Two have already completed their Fellowships and returned to their homes. These are: Dr. Alexander W. Arathoon of Guatemala, who had a Fellowship at the Massachusetts Eye and Ear Infirmary, and Dr. Francisco de Almeida Rosa of São Paulo, Brazil, who studied at the University of Michigan and the New York Eye and Ear Infirmary.

Drs. Andreine Campanella and Maria C. de Carvalho have been appointed by the Institute of Inter-American Affairs to take an ophthalmologic course at the Washington University, St. Louis, Mo.

During the last two weeks of November, Prof. Moacyr E. Alvaro, executive secretary of the Pan-American Congress of Ophthalmology, visited the Argentine and Uruguay. In Buenos Aires, Dr. Alvaro was invited by Dr. Malbran, president of the Argentine Society of Ophthalmology, to preside at the annual meeting of that Society, where Dr. Sená read a paper on "Sulfonamides in ophthalmology." At the Alvear Hospital, at the invitation of Dr. Belgeri, Dr. Alvaro lectured on "How can the ophthalmologist cooperate with the general practitioner in order to obtain a correct diagnosis?" and at the Rawson Hospital at the invitation of Dr. Carlos Damel, head of the Ophthalmological Department of that hospital, Dr. Alvaro gave another lecture on "The advantages of organized ophthalmology." Dr. Alvaro took the opportunity offered by this trip to visit the above-mentioned ophthalmologic services and was also invited to visit the Patronato Nacional de Ciegos under the direction of Dr. B. Courtis, the Santa Lucia Hospital directed by Ibañez Puiggari, the chair of ophthalmology of the Faculty of Medicine of the University of Buenos Aires, directed by Prof. Raul Argañaraz, and the Fernandez Hospital under the direction of Dr. Juan Gallino.

Dr. Alvaro together with Prof. E. B. Demaria visited the eye clinics of the chair of

ophthalmology of the Faculty of Medicine of La Plata, of Rosario, and of Cordoba. In the latter he was received at the local Ophthalmological Society.

In Montevideo, Dr. Alvaro presided at a meeting of the Committee for the Prevention of Blindness of which Prof. Vasquez Barriere is president.

Dr. Juan Verdaguer, Chief of Clinic in the service of Professor Charlin (Santiago de Chile), was appointed Extraordinary Professor of Ophthalmology in the Medical School of the University of Chile. His incorporation thesis dealt with "Detachment of the retina and its treatment."

Dr. M. Uribe Troncoso received an invitation to read a paper at the annual meeting of the Pan-American Medical Association, Washington chapter, and give a lecture on "Gonioscopy, Its development and clinical applications." The meeting was held on March 18,

1944, at the Mexican Embassy, under the presidency of the Ambassador, Dr. F. Castello Nájera, honorary president of the chapter. On the same day Dr. Troncoso was guest of honor at a luncheon at the International Medical Club of Washington, D.C.

OBITUARY

Dr. Enrique L. Graue, a well-known ophthalmologist in Mexico City, and a former director of the Ophthalmic Hospital of Nuestra Señora de la Luz, died in May, 1943, at the age of 72 years. He was born in Mexico City in 1871. After his graduation, in 1897, he traveled extensively in Europe, attending the London clinics and Paris ophthalmic institutions. He was a fine surgeon and a very charitable man, attending the poor patients in the city and in his hospital with devoted care. He was a member of the Mexican Society of Ophthalmology and Otolaryngology. His oldest son, who has the same name, is also an eye specialist and practices in Mexico City.

DEATHS

Dr. Milton R. Barker, Wilmette, Illinois, died February 3, 1944, aged 92 years.

Dr. Edgar Bates, Ogden, Utah, died January 24, 1944, aged 74 years.

Dr. Arthur E. Jessup, Diagonal, Iowa, died January 12, 1944, aged 74 years.

Dr. Waldo N. Lemmon, Hereford, Texas, died January 1, 1944, aged 71 years.

Dr. Frederick M. Spalding, Boston, Massachusetts, died January 24, 1944, aged 73 years.

Dr. Henry R. Slack, LaGrange, Georgia, died January 16, 1944, aged 81 years.

Dr. Roy W. Dunlap, Tulsa, Oklahoma, died January 29, 1944, aged 65 years.

Dr. Halbert H. Acker, Anderson, South Carolina, died January 20, 1944, aged 56 years.

Dr. Horace L. Goodman, Ronceverte, West Virginia, died February 28, 1944, aged 67 years.

Dr. Charles Graef, New York, New York, died February 27, 1944, aged 72 years.

Dr. Arthur C. Haney, Russellville, Arkansas, died December 22, 1943, aged 54 years.

Dr. Frank L. Secoy, Sioux City, Iowa, died January 23, 1944, aged 57 years.

Dr. Daniel H. Bell, Tacoma, Washington, died recently, aged 72 years.

Dr. Joseph W. Ehmer, Crivitz, Wisconsin, died recently, aged 77 years.

Dr. Arthur E. Falkenbury, Whitehall, New York, died January 23, 1944, aged 78 years.

Dr. William J. Holton, Plant City, Florida, died January 7, 1944, aged 60 years.

Dr. Joseph L. Wicks, Evanston, Wyoming, died January 31, 1944, aged 73 years.

Dr. John W. Dean, Glens Falls, New York, died December 18, 1943, aged 75 years.

Dr. Erra D. Stump, Charleston, West Virginia, died March 1, 1944, aged 59 years.

MISCELLANEOUS

The next examination by the American Orthoptic Council will be held in September-October, 1944. The written examinations will be held at various cities in the country on September 7, 1944. Only those passing the written examinations will be permitted to take the oral and practical tests, to be given in Chicago, October 7, 1944. Applications on official forms must be received before August 1, 1944. Address the American Orthoptic Council, 23 East 79th Street, New York 21, New York.

The twelfth semi-annual postgraduate course in "Neuromuscular anomalies of the eyes"

will be given at the Children's Memorial Hospital, Chicago, Illinois, by Dr. George P. Guibor, May 7-12, 1944.

As an addition to the growing number of motion pictures in the field of health education a two-reel film, "Eyes for tomorrow," was produced for the National Society for the Prevention of Blindness, 1790 Broadway, New York City. "Eyes for tomorrow" stresses good general health as a prerequisite for good eyesight, besides dealing with the importance of conservation of vision among school children, methods of treatment of glaucoma and trachoma, importance of prenatal care as a means of reducing blindness caused by syphilis and gonorrhea, and the eye hazards of industry. The film, in 16 and 35 mm., will be distributed in the United States by the National Society for the Prevention of Blindness. Prints in 16 mm. are offered for sale at \$50.00, or rental at \$5.00 per day, exclusive of time in transit.

The American Board of Ophthalmology has announced that examinations will be held in New York on June 2d, 3d, and 5th, and in Chicago on October 5th to 7th. The new address of the Board is 704 Congress Street, Portland, Maine.

The Association for Research in Ophthalmology, Inc., announces its program for the fourteenth scientific meeting, to be held on Tuesday, June 13, 1944, at the Hotel Sherman, Chicago, Illinois.

1. Choline esters with mydriatic and cycloplegic action. Kenneth C. Swan, M.D., and Norman G. White, M.S., University Hospital, Iowa City, Iowa.

2. The dissociation of form and light perception in amblyopia ex anopsia. Hermann M. Burian, M.D., and George Wald, Ph.D., Biological Laboratories of Harvard University.

3. A quantitative test for measuring degree of red-green color deficiency. Louise L. Sloan, Ph.D., AAF School of Aviation Medicine, Randolph Field, Texas.

4. A study of the pathogenicity of diphtheroid bacilli isolated from the human conjunctivae. Charles Weiss, M.D., Isabella H. Perry, M.D., and Marion C. Shevsky, A.B., Mt. Zion Hospital, San Francisco, California.

5. Backflow phenomena in aqueous veins of normal and of glaucomatous eyes. K. W. Ascher, M.D., Department of Ophthalmology,

College of Medicine, University of Cincinnati.

6. Effect of chemotherapeutic agents on cell division of the intact and regenerating corneal epithelium following burns and abrasions in the rat. George K. Smelser, M.D., and V. Ozanics, M.D., Columbia University College of Physicians and Surgeons, New York.

7. Evaluation of the use of penicillin in military ophthalmology. John G. Bellows, Major (M.C.), Billings General Hospital, Fort Benjamin Harrison, Indiana.

Frederick C. Cordes, Chairman
Brittain F. Payne, Major (M.C.)
Secretary (Program)
Conrad Berens
Acting-Secretary-Treasurer

SOCIETIES

The annual congress of the Ophthalmological Society of Egypt was held at the Memorial Ophthalmic Laboratory, Giza, Egypt, on March 15th and 16th. The program consisted of a symposium on "Ulcers of the cornea."

The Florida Medical Association held its seventy-first annual meeting at Saint Petersburg on April 13th and 14th. Among the speakers was Dr. Walter I. Lillie, Philadelphia, who lectured on "Fundus changes in arterial hypertension." Included in the specialty groups which

met during the session was the Florida Society of Ophthalmology and Otolaryngology.

At the annual session of the South Carolina Medical Association Dr. Roderick MacDonald, Rock Hill, presented a paper on "Headache from an eye, ear, nose, and throat standpoint."

The Brooklyn Ophthalmological Society held its regular meeting on April 20th. The scientific program consisted of the following papers: "The pathology of congenital hydrophthalmos and allied conditions" by Drs. Bernard Samuels and Edward Burchell, and "Surgical treatment of congenital glaucoma," by Dr. John H. Dunnington.

PERSONALS

The Warren Triennial Prize of \$500, presented by the Massachusetts General Hospital, was awarded to Dr. David G. Cogan, Dr. V. Everett Kinsey, and Mr. Erwin O. Hirsch, of the Howe Laboratory of Ophthalmology, Harvard Medical School, for the essay "Physiological studies on the cornea."

The University of Minnesota Medical School, Minneapolis, has appointed Dr. Erling W. Hansen, former clinical assistant professor of ophthalmology, to the position of clinical professor and director of the division of ophthalmology at the university.

THE EXOPHTHALMOS OF HYPERTHYROIDISM

A DIFFERENTIATION IN THE MECHANISM, PATHOLOGY, SYMPTOMATOLOGY, AND
TREATMENT OF TWO VARIETIES*

Part I

JOHN H. MULVANY, F.R.F.P. & S.GLAS., F.R.C.S.ENG.,
D.P.M.ENG., M.R.C.P.LOND., M.R.C.O.G.

London

INTRODUCTION

It is hoped that this paper dealing with the differentiation of the exophthalmos of hyperthyroidism into two varieties will prove of some interest to those concerned in its study. Particularly worthy of consideration is the corollary implied in the possible existence of the distinction; namely, the inference that each variety of proptosis constitutes merely one important feature of two unrelated and separate diseases hitherto included under a number of terms in the literature although mostly being confused with thyrotoxicosis.[†] The general application of the latter term to all and sundry forms of hyperthyroidism is partly responsible for the anomaly as the practice tends to obscure the apparent circumstance that, while all varieties of thyrotoxicosis are hyperthyroid, not all instances of hyperthyroidism are examples of thyrotoxicosis. Elsewhere it has been pointed out (Mulvany, 1943) that the various forms of hyperthyroidism occurring spontaneously in man fall into three main categories, thyrotrophic, thyrotoxic, and thy-

ropathic. The first, depending upon pituitary control, is familiar as a physiologic and pathologic occurrence in the latter third of pregnancy and in acromegaly, respectively. The second is exemplified in exophthalmic goiter, a compound expression of hyperthyroidism and sympatheticonia maintained apparently independently of thyrotrophic activity; and the last, arising from local disease of the thyroid gland, is often seen, usually in a transient form, in the early phases of neoplasm or infection or in lymphadenoid goiter. It is expedient for an improved understanding of the problems connected with hyperthyroidism that its composite pathogenesis should be appreciated.

Of these several varieties of hyperthyroidism, two only appear generally to be associated with exophthalmos; namely, thyrotoxicosis proper and one form of thyrotrophic origin. The latter results from increased thyrotrophic activity; but the absence of exophthalmos in pregnancy and acromegaly makes it evident that thyrotrophism *per se* does not lead to proptosis. There is evidence to suggest

* This paper was accepted May, 1938, by the Royal College of Surgeons for the purpose of a Hunterian lecture delivered in February, 1939. A few additional remarks relating to more recent observations have been included.

[†] The term thyrotoxicosis is used in this paper synonymously with Basedow's disease, Graves's disease, exophthalmic goiter, and diffuse, toxic, or hyperplastic parenchymatous goiter.

that another factor, the coöperation of certain sterones, is also essential for the development of exophthalmos in experimental thyrotrophic hyperthyroidism, and it may be assumed on reasonable grounds that the equivalent disorder occurring spontaneously in man possesses a similar pathogenesis. Should this assumption prove correct, the process indicates probably a disturbance of thyroid and sex secretions, as sex function is greatly influenced by certain types of steric activity; but further work is required to elucidate this problem. The present paper, however, is not concerned with the general considerations of pathogenesis but will deal only with the differentiation of the proptosis occurring in this disorder from that associated with exophthalmic goiter.

HISTORICAL NOTE

It is well over 100 years since the attention of the medical profession was directed for the first time to the problem of exophthalmos occurring in association with an enlargement of the thyroid gland. The credit for this discovery is often ascribed to Basedow (1840), although it has been established that the condition was described some years earlier by Parry (1776) and Graves (1835). The anomaly may be explained possibly on the ground that the account given by Basedow was the fullest in point of original observation, particularly in connection with the exophthalmos. Nevertheless, the discoveries of these three observers were independently made and all are therefore deserving of an appreciation by posterity; although, as Osler has remarked, the account left by Parry was so complete and original that it more justly entitles him to the honor of the discovery of exophthalmic goiter than does that of the others.

Be that as it may, the first published explanation of the mechanism thought to be responsible for the development of the

exophthalmos came from the pen of Basedow. This feature, so pronounced in one of his cases that both eyes were lost, was considered by him to be produced by a "strumous hypertrophy" of the retrobulbar cellular tissues, not due to edema or fat, but possibly similar in nature to the morbid process responsible for the association of those peculiar swellings known as areas of "localized myxedema." This interesting observation, based apparently on clinical surmise, was not supported by pathologic evidence, and today it is well known that examination of the orbit at autopsy in the typical case of Graves's disease discloses no indication of increased retrobulbar pressure. The remark, however, is of special interest in view of the recent revival of the theory of *proptusio bulbi a tergo* occasioned by reports of a progressive type of exophthalmos, associated in about half the cases with hyperthyroidism, in which the proptosis has been due unquestionably to increased intraorbital pressure. The majority of these cases have been labelled exophthalmic goiter, but numerous other diagnoses, ranging from idiopathic aseptic thrombosis of the cavernous sinus to polyglandular disturbance, and from exophthalmic ophthalmoplegia to idiopathic myositis of the extraocular muscles, have been attached. These varied opinions are in contrast to the singleness of the pathologic and clinical features which in their uniformity contribute strong support for believing the condition to be distinct from exophthalmic goiter.

Following the pioneer work on the subject, the growth of knowledge and interest progressed smoothly. Shortly after the publication of Basedow's famous article, there appeared a report by Cooper (1849) containing an explanation of the mechanism which produced exophthalmos. The suggestion was that the proptosis depended upon two factors; namely, an ab-

sence of the proper tonicity of the muscles which served to retain the eyes in their natural position in the orbit, and the presence of venous congestion of the retrobulbar cushion confined to the tissues therein and not extending to the eyes. As with Basedow's idea, the theory is of interest because it appears certain that weakness of the voluntary eye muscles plays an essential part in the development of proptosis in exophthalmic goiter; and, indeed, if the presence and function of the unstriated musculature of the orbit had been known in Cooper's day, it is not unlikely that the mystery of the mechanism would have then been solved.

ROLE OF UNSTRIPED ORBITAL MUSCULATURE

The experiments of Claude Bernard (1858), in which retraction of the lids and proptosis in rabbits were noted to follow stimulation of the distal cervical sympathetic nerve, and the publication by Müller (1858) of the anatomic work on the smooth muscle of the orbit gave a further stimulus to thought on the subject. Aran (1860) put forward the view that the proptosis of Graves's disease was produced by a contraction of the unstriated orbital muscle, an idea at first received with enthusiasm until it became known that stimulation of the cervical sympathetic in man did not cause exophthalmos although lid retraction and dilatation of the pupil were evident. Thus, Jaboulay (1898), Jonnesco (1897), and more recently Pochin (1939) convinced themselves on this point by practical experiment in the course of operations on the neck, and Müller (1861) and Wagner (1859) arrived at a similar conclusion by using the heads of newly decapitated criminals.

The first experiments on a more scientific basis intended to solve the problem were carried out by MacCullum and Cor-

nell (1904). These investigators exposed the orbit of the dog and found that this animal possessed a well-developed periorbital membrane which extended forward in the shape of a cone from the region of the optic foramen to the margins of the orbit. They demonstrated that this membrane contained a large amount of unstriated muscle and that protrusion of the globe followed stimulation of the cervical sympathetic which induced a wave of peristalsis to pass along the cone. Transverse section of the cone led the peristalsis to cease at the edge of the sectioned area and prevented the development of a proptosis. Similar experiments have been conducted by Code and Essex (1935) who confirmed the findings of MacCullum and Cornell and demonstrated also the presence of a rise of pressure within the fascial cone during the period of stimulation.

MacCullum and Cornell formed the opinion that "although no certain conclusions could be drawn from their work, the possibilities were perhaps more closely defined." It seemed, however, that there was a failure to appreciate the anatomic differences between the orbits of man and the dog, which are of such a type as to preclude the application of a common mechanism to both. In the dog, sheep, and certain other animals, the periorbital membrane forms a well-developed muscular structure characterized by a strength and mobility not present in man. The reason for this distinction lies in the fact that the bony socket in these animals is rudimentary, being formed by bone only on its inner wall, so that a strong periorbital membrane is essential. Hence it is not a difficult matter for a contraction of this powerful and mobile structure to give rise to proptosis. In the ape and man, however, the position is quite different, as the presence of a regular bony socket obviates the need for an additional muscular support.

In them, the periorbital muscular elements are vestigial and rendered still less effective in contraction by a close attachment to the orbital walls, a point confirmed by the fact that stimulation of the cervical sympathetic nerve in the ape, as in man, does not lead to protrusion of the globe. On this account it is safe to assume that the periorbital smooth muscle plays no significant part in the development of proptosis in exophthalmic goiter.

Thus it was that the unsatisfactory nature of the anatomic basis of the theory built around Müller's periorbital muscle led to a more thorough examination of the orbit, and in 1907 Landström was able to demonstrate by means of serial sections in three planes the presence of smooth muscle in the anterior half of the orbit. This took the form of a cuff surrounding the front half of the globe, being attached anteriorly to the back of the orbital septum and extending backward to the region of the equator of the eye, where it was inserted into fascial expansions given off by the recti muscles at their point of attachment to the globe. As a result of these investigations, Landström was able to state that this muscular cuff could by its contraction exert traction on the globe, and he ascribed the exophthalmos of Graves's disease to this factor. The theory, however, although anatomically sound, still failed to explain why stimulation of the cervical sympathetic in man does not produce proptosis.

It was evident, therefore, that some other factor was required to supplement the action of the orbital unstriated musculature, and in 1935 Plummer and Wilder demonstrated its nature. In a closely reasoned article, these observers were able to establish in exophthalmic goiter the existence of a positive correlation between the amount of myasthenia and the degree of exophthalmos present. They expressed the opinion that it would be possible for a

spastic contraction of Müller's orbital muscle to produce exophthalmos in the presence of weakened recti muscles. Some criticism of this view is justifiable from the fact that Müller's orbital (better termed periorbital) muscle is hardly capable of influencing the position of the eye in any circumstances, but there is no reason why Müller's palpebral muscles and Landström's muscular cuff could not achieve this in the presence of a weakened voluntary musculature within the orbit. This aspect of the problem will be considered again later in connection with the discussion of the actual mechanism concerned in the production of the proptosis.

THE ROLE OF THE THYROTROPHIC HORMONE

While these theories concerning the part played by the unstriated musculature of the orbit were being developed, there began to appear in the literature reports of cases of progressive bilateral exophthalmos associated with peculiar pathologic changes in the voluntary ocular muscles. About half the cases were stated to have been accompanied by thyrotoxicosis, but in the others this was not noted or else its association was doubtful. The first of these cases to give rise to general interest was described by Foster Moore (1920). The patient, a woman aged 53 years, had a severe proptosis which resisted lid-suture and was still urgently in need of further treatment. The author thereupon exposed the orbit through the lower fornix and removed as much as a heaped-up teaspoonful of edematous fat, after which it became possible to approximate the lids. He noted that the recti muscles, instead of being thin flat ribbon-like structures were "greatly swollen fusiform bellies not quite so stout as the last joint of one's little finger." It was obvious that in this particular case the proptosis was due to retrobulbar pressure,

and the author concluded, in view of the unusual features, that a modification of this process was the probable mechanism responsible for its appearance in Graves's disease. The histologic examination of a portion of the inferior-oblique muscle, removed at the time, disclosed the presence of a certain type of morbid change which in recent years has become more familiar mainly through the writings of Burch (1929) and Naffziger (1933) and which has been associated clinically with a progressive and severe type of exophthalmos, often complicated by corneal ulceration and allied phenomena. A peculiar and common feature in many of these cases was that the condition had apparently been induced or accentuated by the performance of a thyroidectomy for the relief of hyperthyroidism, an aim successfully achieved.

Some light was shed on these events by the work of Schockaert (1932), of Loeb and Friedman (1932), and of Marine and Rosen (1933) who showed that hyperthyroidism with exophthalmos could be produced by an injection of pituitary extract containing thyrotrophic hormone. Naturally, the idea grew that the pituitary gland might be responsible, if not for Graves's disease, at least for the development of the exophthalmos. A great deal of work in this direction has been done without settling the problem, but the view relating to the pituitary genesis of the disease has gained strength. Nevertheless, caution is required in the acceptance of the hypophyseal theory, as there is strong evidence against it with little or nothing conclusively or incontrovertibly in its favor; so that the possibility of thyrotoxicosis being governed by some factor other than the thyrotrophic hormone should be borne in mind.

The most important contributions in support of the pituitary genesis of thyrotoxicosis are probably those of Smelser

(1937) and Marine (1938). The former was able to examine the orbital tissues in certain patients thought to have Graves's disease and to compare the pathologic changes therein with those he had observed experimentally in the orbits of guinea pigs treated with thyrotrophic hormone. The results of his observations were sufficiently conclusive to enable him to say that the experimental type, with certain minor differences, closely resembled the clinical variety. The tissue response, including the muscle hypertrophy and edema of the connective tissue, was general and included the characteristic round-cell infiltration which has come to be recognized as an essential part of the pathologic picture. Further, Smelser stated that edematous infiltration of the retrobulbar tissues had been repeatedly demonstrated in, and presented as, the cause of exophthalmos associated with Graves's disease; a statement requiring modification, as the vast majority of orbital examinations at autopsy fail to reveal any such causative factor. However, as Smelser remarked, exophthalmos has been found with all ranges of basal metabolic rate and particularly extreme cases of the progressive variety have followed thyroidectomy when the basal metabolism was subnormal. The conclusion therefore drawn by this observer was that the mechanism of exophthalmos in hyperthyroidism and hypothyroidism was the same, although the thought that cases activated by a different mechanism, possibly sympathetic excitation, might exist.

Similar views are held by Marine (1938) who claimed that thyroid insufficiency, either relative or absolute, is one of two essential factors underlying the development of the exophthalmos in Graves's disease; by Brain (1938) who stated that in exophthalmic goiter the exophthalmos is not the result of hyperthyroidism, and more recently by Eden

and Trotter (1942) who concluded that the exophthalmos occurring in diffuse toxic goiter is extrathyroid in origin. Such views, so contrary to what is generally accepted in relation to the proptosis of exophthalmic goiter, depend to a certain extent on an idea that hyperthyroidism is a single entity; on a failure to perceive that all varieties of hyperthyroidism not being instances of thyrotoxicosis, the accompanying proptosis may not be consistently uniform in etiology; on lack of consideration that thyrotoxicosis, being fundamentally a hyperthyroid disease, the associated exophthalmos equally must be thyrotoxic in nature; and lastly on a faulty interpretation of the fact that while a certain variety of thyrotrophism may lead to hyperthyroidism and exophthalmos, the latter depends on the presence of the thyrotrophic hormone and not of the thyroid gland—hence its appearance with all ranges of basal metabolism. The true position is that the exophthalmos of hyperthyroidism may be either thyrotoxic or thyrotrophic, but the progressive proptosis of hypothyroidism can be only hypophyseal in origin.

The work of Marine is of great importance and enlightenment. In 1932, this observer, working in conjunction with others, noticed that exophthalmos associated with goiter developed in certain pubertal rabbits fed on a diet of alfalfa hay and oats or after a daily injection of 0.1 c.c. of methyl cyanide. The fact that the exophthalmos did not develop until large parenchymatous goiters had appeared and that such goiters were associated with hypertrophy of the pituitary body of the type seen after a thyroidectomy suggested there was a close relationship between thyroid deficiency and increased activity of the anterior pituitary and between the latter and the appearance of the proptosis. Indeed, in the above experiments and in guinea pigs treated with

injections of anterior pituitary extract, removal of the thyroid gland was found to facilitate the development of the exophthalmos, a phenomenon capable of explanation on the ground that the injection process is supplemented by the stimulus to increased pituitary output induced by the operation.

Another highly important observation made by Marine was that a greater degree of exophthalmos appeared in those animals which were most active sexually. This prompted him to investigate the effects of cryptorchidism and gonadectomy on the development of the exophthalmos. His results showed that while cryptorchidism had no effect, gonadectomy caused a regression of the proptosis when present or prevented its appearance in others. Injection of the androgens, particularly of testosterone, effectively replaced the missing orchids but the estrogens were inert. These findings led him to conclude that the degree of functional activity of the interstitial cells of the testes was an important factor in determining the development of the exophthalmos and to formulate the view that "thyroid insufficiency (relative or absolute) and anterior pituitary hyperactivity appear to be two of the essential factors underlying the development of the exophthalmos of Graves's disease . . . and that an increase in the functional activity of the interstitial cells and possibly of the adrenal cortex is necessary." The apparent paradox in the statement follows the practice of accepting an experimental pituitary hyperthyroidism as being the equivalent of Graves's disease. It is quite certain that thyroid insufficiency is not a feature of thyrotoxicosis and that the degree of exophthalmos often bears some relation to the height of the metabolic rate. It may be recalled also that there is no evidence of pituitary overactivity in Graves's disease, the gland

often being small and sometimes atrophied, and the adrenal cortex may be degenerated and the gonads relatively inactive. Marine's remarks, however, can well be applied to the experimental variety of gonadothyrotrophism and his observations concerning the activity of the adrenal cortex become of special interest because it is possible that this structure may form the source of the essential sterone in women after the menopausal atrophy of the gonads.

Nevertheless, Marine's experiments are highly important because for the first time an explanation is offered to account for the absence of exophthalmos in the other varieties of thyrotrophic hyperthyroidism. As noted earlier, acromegaly and pregnancy are only very rarely accompanied by exophthalmos although the basal metabolism may be raised as much as 50 percent by thyrotrophic stimulation of the thyroid gland. In certain instances of myxedema, also, there is an increased amount of thyrotrophic hormone in the bloodstream, yet exophthalmos remains notably absent. It is patent, therefore, that the thyrotrophic hormone is only partly responsible for the development of the proptosis, and that some additional factor is also essential. The work of Marine affords grounds for believing this to consist of certain of the androgens. It is probable that the hyperthyroidism and exophthalmos induced by injections of anterior pituitary extract (which however purified contains gonadotrophin as well as thyrotrophin) are the outcome of an experimental gonadothyrotrophism and not of a simple thyrotrophism; and it is not unlikely that the equivalent state in man possesses a somewhat similar pathogenesis. Hyperthyroidism, a feature both of exophthalmic goiter and thyrotrophic exophthalmos, is relieved in each instance by a thyroidectomy; but the effect of the operation on the exophthalmos is differ-

ent in the two diseases. In the first, the proptosis is relieved or not altered; in the second, it may remain stationary or become greatly increased in severity owing to the raised thyrotrophic activity of the pituitary gland resulting from the absence of the thyroid gland. Both experimentally and in man a rapid progression of the proptosis in the thyrotrophic variety may follow a thyroidectomy when the basal metabolism is often below normal, and this fact has given rise to the erroneous belief that hyperthyroidism is not an essential factor in the development of the proptosis in thyrotoxicosis and that the mechanism of the exophthalmos in both hyperthyroidism and hypothyroidism is similar. The true position is that hyperthyroidism is necessary for the appearance of the proptosis in thyrotoxicosis but in the thyrotrophic variety hyperthyroidism plays no essential part in its development although remaining an associated feature of the disease.

Such has been the history of events leading up to the present-day attitude in which the phenomenon of exophthalmos associated with hyperthyroidism is thought to possess a single pathogenesis. Observations in connection with the interpretation of the recent experimental work which has confirmed or conduced to this idea have also been included. It remains now to examine the possibilities of the differentiation of the two varieties of exophthalmos which for convenience have been termed respectively thyrotoxic and thyrotrophic, indicating thereby without claim to etiologic comprehensiveness an essential component of the pathogenesis.

ANATOMIC FACTORS CONCERNED IN THE MAINTENANCE OF THE NORMAL POSITION OF THE EYE

Before consideration of the possible factors concerned in the development of exophthalmos in hyperthyroidism, it may

be useful first to examine the mechanism which normally maintains the eye in its natural position. Briefly, it is known that the globe is retained firmly within the capsule of Tenon by means of numerous fine trabecula stretching between the two structures and by various expansions which attach themselves to the tendons of the ocular muscles as they pass through its wall. The capsule itself is steadied by bilateral attachments to the orbital tubercles and is reinforced below by a thickening of its anterior portion, known as the ligament of Lockwood. All these structures serve to stabilize the position of the eye without affecting its range of movement. There are, however, other factors of a less fixed character which are capable of influencing the position of the globe. The following are the three most important:

I. *The tone of the voluntary ocular muscles.* These muscles consist of the four recti and the two obliques and their function is concerned with more than just eye movement. In the words of Whitnall (1921) "... The eye is delicately poised . . . and a state of equilibrium is maintained by the tone of the extraocular muscles. As a whole, the four recti may be regarded as retractors of the ocular bulb; they are antagonized by the obliques which, from their origins and the direction of their fibers, act as protractors and this is the active element maintaining the equilibrium of the globe." Rarely, the obliques are able to dissociate their power of contraction from that of the recti, allowing a state of voluntary exophthalmos to be produced. Normally, however, this dissociation is impossible and the combined tone of the recti muscles is sufficiently powerful to resist any tendency to proptosis, even in the face of most intense stimulation of the cervical sympathetic nerve. It is interesting, therefore, to recall that in certain conditions, such as myasthenia gravis and neurosyphilis, in which there may be an associated weakness or palsy of the eye muscles, exophthalmos may be present as a clinical feature. In thyrotoxicosis, the presence of ocular-muscle weakness is closely related to the development of the proptosis and yet more nearly to the disturbance of eye movement.

II. *The width of the palpebral fissure.* It is a well-known phenomenon that in normal

people wide retraction of the lids may be accompanied by a slight degree of proptosis, due doubtless to a lessening of pressure on the anterior surface of the globe occasioned by the tonic contraction of the orbicularis oculi. The extent of exophthalmos which may follow this movement depends on the relative grades of tone existent in the sphincter and the retracting muscles, and it may be expected, therefore, that the phenomenon will be more readily seen in thyrotoxicosis, owing to the associated extraocular weakness. This is generally the case, and excellent illustrations of the fact are available in an article by Tilley (1926) in which an excursion of the globe to the extent of 4 or 5 mm. was noted to follow the maneuver. With the eyes closed or opened in normal fashion, very little exophthalmos was visible; but as the lids were widely retracted the eyeball moved rapidly forward and appeared to be protruded through the enlarged fissure. Hence, the width of the palpebral fissure in thyrotoxicosis often bears some relationship to the degree of exophthalmos, particularly when associated with lagophthalmos due to sphincter weakness.

III. *The bulk of the retrobulbar tissues.* Normally, the retrobulbar fibro-fatty tissue accommodates itself to the space within the extraocular cone of muscles, being equitably disposed to exert an even pressure on the rear of the globe. Slight alteration in the volume of this cushion may modify the position of the eye, as may be recalled from the hollow-eyed appearance associated with wasting or the bulging orbits of the obese alcoholic. In thyrotoxicosis, there is no real increase in the bulk of the retrobulbar tissues, as has abundantly been proved at autopsy, although the intraorbital fat may be more loosely spread and indeed increased in the degenerating muscles. Hence, in exophthalmic goiter, this factor plays no part in the development of the proptosis. On the other hand, the exophthalmos of thyrotrophic origin is produced solely by an expansion of the intraorbital contents taking place within the bony confines of the orbit.

Of these three factors therefore capable of influencing the position of the eye, it may be stated that in thyrotoxicosis the tone and strength of the recti muscles are of primary importance, the width of the palpebral fissure of minor character, and the volume of the retrobulbar tissues of no consequence at all. Conversely, in the thyrotrophic variety, the first two items exert no influence, the last-named factor

constituting the sole operative agency.

With these brief anatomic considerations in mind, the differentiation of the two types of exophthalmos will follow.

A. THYROTOXIC EXOPHTHALMOS: ITS MECHANISM, PATHOLOGY, SYMPTOMATOLOGY, AND TREATMENT

I. MECHANISM OF THYROTOXIC EXOPHTHALMOS

It may be remarked that the most important guiding observation in this respect has been the incontrovertible fact that in the numerous autopsies conducted on persons dying of typical thyrotoxicosis nothing very much of note has been discovered in the orbit. It is important to bear this fact in mind for there has been a tendency to overlook it, following the description of the orbital changes in animals consecutive to the administration of anterior-pituitary extracts and the discovery of identical findings in the human orbit in certain cases of progressive post-thyroidectomy exophthalmos. In both these states the proptosis unquestionably has developed in response to a raised intraorbital pressure, and it has been assumed in certain quarters that the exophthalmic mechanism in thyrotoxicosis is due to a similar morbid process. This assumption is erroneous. The development of pressure in the thyrotrophic variety is brought about by constant alterations in the eye muscles, comprising increased girth, edema, fibrosis, and round-celled infiltration. These distinctive features are absent in the thyrotoxic orbit, often there being no naked-eye abnormality. This definite and conclusive finding assists one to dispose of those theories in which the mechanism is based upon increased retrobulbar pressure. It may be emphasized that neither clinically nor pathologically is there ever anything in typical thyrotoxicosis to indicate that in-

creased retrobulbar pressure is the cause of the proptosis, and it is of little value to consider any hypothesis which does not take this fact into account. Consequently the logical conclusion may be accepted that the responsible mechanism of the proptosis, not being governed by pressure from behind, must depend upon forward traction of the globe. Allusion has been made to two factors, sympathetic overaction and ocular-muscle weakness, which have been thought capable of producing exophthalmos in thyrotoxicosis. It remains now to examine their likelihood.

THE SYMPATHETIC COMPONENT. It has been maintained since 1858 that sympathetic overaction plays an essential part in the development of proptosis in thyrotoxicosis. This idea has grown because sympatheticonia is a constant accompaniment of the disease; because experimental stimulation of the cervical-sympathetic nerve in animals has produced proptosis and lid retraction, and because the absence of an obvious mechanical or voluntary force implies the functioning of involuntary effort. Recently a suggestion that spasm of the levator palpebrae is responsible for upper-lid retraction has been made by Pochin (1939b) on the ground that the effects of stimulation of the cervical sympathetic in man, comprising dilatation of the pupil, retraction of both lids but not exophthalmos, are not seen in thyrotoxicosis. There is little evidence to support this view, and the relief of lid retraction sometimes following cervical sympathectomy is a strong pointer against the agency of striated muscle; at the same time the three points of distinction raised are capable of explanation. The main difficulty in ascertaining the part played by the sympathetic system has been to establish the anatomic basis of the mechanism involved; hence it is of some consequence to find that the unstriped

musculature of the anterior half of the orbit as described by Müller and Landström is suitably disposed to effect forward traction on the globe.

Landström's orbital muscle consists of a cone of unstriated muscle surrounding the front part of the globe. It extends from the back of the orbital septum an-

confused with Müller's orbital muscle, consist of small bands of unstriated muscle in the region of the lids and appear to comprise specialized portions of Landström's muscle. The superior muscle is the more important and corresponds in position to the middle division of the insertion of the levator palpebrae, stretch-

Fig. 1 (Mulvany). Landström's muscle. Sections from anterior orbit showing the extensive and close attachment of the smooth muscle (m) to the globe (Landström, 1907).

teriorly to the region of the equator of the globe, where it is connected to fascial expansions derived from the ocular muscles near their point of attachment to the eye. The muscle is widely distributed and of surprising strength, as may be gathered from a perusal of Landström's original work (fig. 1). The main fasciculi lie close to the globe and many are inserted directly into fascial investments of the ocular muscles. The muscle gains its power from the concentric arrangement of numerous bundles exerting a short direct pull.

Müller's palpebral muscles, not to be

ing from the region of the tendon of the superior-rectus muscle to the tarsus, to which it is attached. Lid retraction in Graves's disease is attributed to spasm of this muscle, but the practicability of its contraction contributing to the development of the exophthalmos appears to have been overlooked. The effect, however, is conveyed to the upper pole of the globe through the intimate fascial connection which exists between the levator and the tendon of the superior rectus (fig. 2). The function of this band normally is to facilitate raising of the lid on elevation of

the eye, and its practical importance is emphasized in the lid retraction or ptosis which may follow recession or an advancement of the superior-rectus tendon, respectively. Spasm of the unstriped muscle in this position effects a pull between the tarsus and the point of insertion of the upper rectus; hence, in producing lid

the eye is rotated downward. Spasm of these fibers exerts a direct pull between the tarsus of the lower lid and the under surface of the globe.

The tension of these small muscles of Müller is not insignificant, as may be gauged in certain instances when attempting approximation of the lids. Working

Fig. 2 (Mulvany). Sagittal section through orbit, showing Müller's palpebral muscles stretching between the lids and the tendons of the upper and lower recti muscles (semidiagrammatic).

retraction, there is a tendency also to proptosis.

In the case of the inferior palpebral muscle, a more direct mechanism is apparent although the fibers are less well developed. The smooth muscle is contained in the fascial expansion from the tendon of the inferior rectus to the lower lid, the normal function of which is to assist depression of the lower lid when

in conjunction with Landström's muscle, the combination is able to effect a steady forward pull on the globe (fig. 3) and should be capable of producing all degrees of exophthalmos provided there is coincidentally sufficient impairment of tone of the voluntary muscles. It should be appreciated that the proptosis is achieved not by the active contraction of opposed sets of muscles but by the steady unflag-

ging pull of small, spastic fibers operating against weakened and hypotonic ones.

COMPONENT OF OCULAR-MUSCLE WEAKNESS. The possibility of weakness of the eye muscles as a factor in the mechanism

Fig. 3 (Mulvany). Diagram illustrating direction of pull of anterior orbital smooth muscle. A, Landström's muscle; B, Müller's palpebral muscles.

of thyrotoxic exophthalmos was pointed out in 1849 by Cooper. The idea has since presented itself to several observers, notably Moebius (1886), Lemke (1894), Sainton and Hesse (1931), and recently Plummer and Wilder (1935).

Generalized myasthenia, of which the eye-muscle weakness forms partly a local expression, is a fairly constant accompaniment of thyrotoxicosis, although in its mild form it may pass unnoticed by the patient and remain unrecognized by the clinician. Commonly it is manifested clinically by a variable amount of weakness of the quadriceps femoris or of the ocular muscles, but occasionally severe types are encountered in which the main disturbance may be noted in the limbs, giving rise to a paraparesis, as described by Charcot (1885), or in the muscles supplied by the cranial nerves, in particular those of the eye. In grave cases death may occur from bulbar asthenia. Hence it is not surprising to find these severe grades of thyrotoxic myasthenia erroneously spoken of as myasthenia gravis complicating exophthalmic goiter, a conclusion which overlooks the fact that myasthenia, whatever its cause, is no more than a symptom indicating a facilitation of the choline-esterase process at the neuro-

muscular junctions and does not constitute a disease in itself. Thus there are at least two other unrelated conditions which may present a typical picture of myasthenia gravis. For instance, the injection of an appropriate dose of curare into a vein induces a state of muscular weakness, initiated by diplopia and bilateral ptosis and followed rapidly by loss of power over the distribution of the remaining cranial nerves, weakness of the arms and legs, and finally by respiratory failure due to intercostal and diaphragmatic paralysis. The condition is relieved by an injection of prostigmine. In other words, "myasthenia gravis," rather "*acceleranda*," can be reproduced by an agent known to interfere with the proper functioning of the myoneural junction and cured by another which restores its normal operation. Another example of typical "myasthenia gravis" not uncommonly occurs in connection with a tumor of the thymus gland, and it is not improbable that it also would be cured by the removal of the diseased organ.

The essentially thyrotoxic nature of the muscle weakness in exophthalmic goiter is shown in the relief afforded by a thyroidectomy or occurring during a remission of the disease. Thyrotoxic myasthenia, therefore, although presenting many similarities to myasthenia gravis, deserves to be distinguished from that condition. Points of difference are seen in the response to rest and prostigmine, which is reduced in effect and duration and may be absent in the case of the ocular palsies. The alteration is probably caused by the hypotonia and persistent weakness occasioned by the widespread degenerative process present in the muscles and nerves.

The eye muscles undoubtedly suffer in greater measure from the toxic agent than does the rest of the skeletal musculature. The reason for this selectivity is a matter for conjecture although it is possible to advance three suggestions:

(a) The eye muscles are composed of a special type of fiber not to be found elsewhere in the body (Woollard, 1930-1931), being of a fine and delicate structure richly supplied by nerves. It would be consistent with this refinement of make-up for these muscles to be associated with

properties of a less durable nature than the coarser type of fiber found elsewhere.

(b) The eye muscles are the only muscles in the body capable of responding to a nonspecific chemical stimulus while the nerve supply is intact. Other skeletal muscles will not contract when so stimulated unless the nerves have degenerated, as after section, or before they have grown into the muscles, as in the fetus. If, therefore, the eye muscles are more susceptible to chemical stimuli than any of the others, it would not be unreasonable to suppose that they would be more readily affected by a chemical toxin or toxemia, of which thyrotoxicosis is a first-class example. This view receives strong support from the fact that the type of degenerative change in the ocular muscles is out of all proportion to anything found elsewhere in the body.

(c) The abundant nerve supply is greatly affected by the morbid process taking place within the muscle bundles, often showing gross deterioration, and even disintegration, particularly in the finer terminal divisions. There can be no doubt that this disorganization of nerve supply is not without consequence upon the functioning of the muscles, and its extensive distribution within the eye muscles accounts partly for the greater disturbance of movement.

CLINICAL CONSIDERATIONS. Strong clinical confirmation of the influence of ocular-muscle weakness on the development of thyrotoxic exophthalmos has been presented by Plummer and Wilder (1935). These observers examined the problem by ascertaining the possibility of correlating the degree of weakness present as tested by a carefully graded series of exercises of the quadriceps and the degree of exophthalmos. The basis of the correlation was presumed to rest upon the assumption that the loss of strength in the

quadriceps would be paralleled by a similar loss in the extraocular muscles which would predispose to forward dislocation of the globe. Some 2,000 cases were examined and the results of their observations enabled them to state that a positive correlation as outlined above existed. Thus in those cases in which no weakness of the quadriceps was detectable clinically, the percentage of exophthalmos present was 44; but in those in which weakness was evident, the frequency of the proptosis varied between 53 percent and 63 percent according to the degree of myasthenia present. The incidence of exophthalmos was therefore 10 percent to 20 percent higher in those cases with detectable myasthenia and in the main corresponded with the more severely toxic patients, the ratio of the proptosis falling concurrently with the rate of the metabolism.

B.M.R.	Cases with Exoph- thalmos	Cases with no Exoph- thalmos	Ratio
+70-+80	102	55	1.86 to 1
+50-+60	213	145	1.46 to 1
+30-+40	163	195	0.83 to 1
+20-+30	115	155	0.74 to 1

(Modified from Plummer and Wilder, 1935)

In certain instances of exophthalmic goiter, the loss of tone in the ocular muscles is so great that a sneeze or nod of the head may result in complete luxation of both globes in front of the lids and in their replacement, which is usually not difficult, the marked hypotonia and absence of increased intraorbital pressure may be clearly appreciated. On the other hand, the eye muscles may be so little affected that no exophthalmos develops.

EXPERIMENTAL CONSIDERATIONS. Additional information on the mechanism of thyrotoxic exophthalmos may be obtained from an examination of experimental evidence. It is known that feeding with

thyroid extract in animals does not lead to exophthalmos, and the finding may be explained on the basis that a state of hyperthyroidism is produced without an accompanying sympatheticotonia; but it is possible in these animals and also in man rendered artificially hyperthyroid by thyroid medication to induce a proptosis by the administration of a sympathomimetic drug. The experiments of Labbé and others (1931, 1933) have shown this. Labbé found that in dogs a dose of ephedrine equivalent to 0.5 mg. per kilogram of body weight was followed only by a questionable degree of proptosis, but that if thyroxine were given intravenously beforehand a marked exophthalmos, not dependent on increased retrobulbar pressure or edema, was produced. This exophthalmos, typically "basedowienne," could be made to recede regularly under the stimulating influence of yohimbine. Thus the coöperation of smooth-muscle spasm and extraocular-muscle weakness was effectively demonstrated; but the investigators carried their experiments a stage further by testing their views on the human being. The patient, an obese woman, had been taking daily a large dose of thyroxine (10 mg.). Marked signs of hyperthyroidism were present when the patient was given 50 mg. of ephedrine. Within five minutes, a prominent exophthalmos, more marked on the left side, had appeared and persisted for two hours. These observers also found that in other patients with exophthalmic goiter the administration of ephedrine accentuated the proptosis.

Equally instructive was the case described by Sainton and Hesse (1931) in which exophthalmos developed in a myxedematous patient as a result of treatment with adrenalin and thyroxine. The patient, with a long-standing case of myxedema, had been receiving a daily injection of 1 mg. of thyroxine. As a result

of treatment the pulse rate accelerated and the basal metabolism rose from -30 percent to -6 percent but fell later to -14 percent in spite of continued dosage. Thereupon the amount of thyroxine given daily was doubled and supplemented by adrenalin. Eight weeks later, the pulse rate had risen to 100, about 18 pounds in weight had been lost, and the basal metabolism was +59 percent. Bilateral exophthalmos was present and "le symptôme basedowien" was complete. On cessation of the adrenalin administration, but continuation of the thyroxine, the exophthalmos disappeared although the patient remained hyperthyroid.

In conclusion it may be stated that the anatomic, experimental, and clinical evidence accords well in favor of a mechanism based on sympathetic overaction and extraocular-muscle weakness, while there is very little that can be opposed to the view.

RELATION OF COCAINE TO EXOPHTHALMOS. Although not strictly relevant to the subject on hand, the rationale of the exophthalmos associated with the conjunctival instillation of cocaine merits a few words. The protrusion is accompanied by lid retraction and submaximal dilatation of the pupil, the light reflex remains and the dilating action of atropine is not opposed. These effects are not produced, as is sometimes stated, by local sympathetic stimulation, for cocaine has no effect on the sympathetic system anywhere else in the body and its action is not prevented by the previous administration of atropine. Cocaine, however, does possess the property of stimulating smooth muscle, and it seems that its effect on the pupil and lids is produced in this way by local permeation although this action in itself does not account for the proptosis nor explain why the ciliary muscle and the sphincter pupillae are relatively unaffected. Concerning the exophthalmos, however, it may be explained that the drug exerts constantly a depressant effect on striped muscle, even in the most dilute solutions, affecting excitability, contractility, and tone. This action is due to a direct effect on the muscle fiber or the receptor organ because it can arrest the action of drugs such as veratrine and quinidine which give rise to a contraction by acting on the myoneural junc-

tion. Absorption from the conjunctiva takes place through three channels, one of which comprises the lymph spaces around the extraocular muscles. Hence the tone of these striped muscles is reduced in consequence and a slight degree of exophthalmos may appear in response to the local stimulation of the anterior orbital smooth muscle. In connection with the subdued action of the drug on the ciliary and sphincter muscles, it may be assumed that its stimulating effect on the unstriped fibers of these muscles is countered to

tion." It was added that the muscles and nerves showed no histologic abnormality, and there was no mention of edema. This statement is only partially correct, for fatty degeneration can be made out in the muscle fibers which together with the nerves show many histologic alterations. Askanazy (1898) found extensive changes in many parts of the skeletal musculature, comprising loss of striation to absorption of entire muscle fibers. A striking feature was a widespread lipomatosis of the voluntary muscles. Later, Dudgeon and Urquhart (1926)

a certain extent by a depressant effect on the oculomotor end-plates, so that the purely sympathetic-supplied dilator is relatively freer to respond.

II. PATHOLOGY OF EYE-MUSCLE CHANGE IN THYROTOXICOSIS

One of the earliest inquiries into the condition of the eye muscles in Graves's disease was made by Silcock (1886). His observations appertaining to a severe case showing advanced proptosis with almost complete immobility of the eyes were as follows: "There was nothing abnormal in the orbits except most noticeably a yellowish patchy discoloration of the recti and obliques which microscopical examination proved to be due to diffuse fatty infiltration, the muscles themselves though somewhat pale showing no trace of fatty degenera-

tion." It was added that the muscles and nerves showed no histologic abnormality, and there was no mention of edema. This statement is only partially correct, for fatty degeneration can be made out in the muscle fibers which together with the nerves show many histologic alterations. Askanazy (1898) found extensive changes in many parts of the skeletal musculature, comprising loss of striation to absorption of entire muscle fibers. A striking feature was a widespread lipomatosis of the voluntary muscles. Later, Dudgeon and Urquhart (1926)

examined the muscle in eight cases of Graves's disease and found changes which were attributed to chronic interstitial myositis. There was a proliferation of the interstitial cells and atrophy of the fibers in varying degrees. A small number of lymphorrhages were found, being small in size and most frequent in the eye muscles.

It is remarkable that in these contributions and in others that have since appeared on this subject, no mention has been made of the nerve degeneration which often equals in intensity the muscle changes.

Briefly, the pathologic changes may be summarized as follows: Inspection reveals the muscles to be thin and sometimes pale, occasionally showing the patchy discoloration noted by Silcock. Microscopy shows a widespread and often extensive degeneration of the muscles and their at-

tendant nerves leading to the ultimate destruction of both (figs. 4-8). The muscle fibers show loss of striation, fibrillation, and granulation of the sarcoplasm followed by its absorption. This takes place either as a result of fragmentation, portions of fiber retaining a few nuclei breaking off, or by a more gradual process involving the whole length of a fiber, the density of which lessens until the fine sup-

ply (fig. 5). The neurilemma becomes granular and undergoes absorption so that in transverse section the fiber appears as an irregular ring with a nucleus placed rather eccentrically. Proliferation of the neurilemmal cells is also evident and often exceeds that of the muscle sheaths (fig. 6). These cells sometimes assume a pear-shaped form having a granular nucleus. Others resemble a lymphocyte but

Fig. 5 (Mulvany). Eye muscle from thyrotoxicosis. Swelling of (n.f.) nerve fiber with granulation of neuroplasm. Slight proliferation of nuclei of neurilemmal sheath.

Fig. 6 (Mulvany). Thyrotoxic eye muscle. Degeneration of muscle (m.f.) and nerve (n.f.) fiber in close proximity. Note disorganization of both, the nerve fiber showing marked reduplication of neurilemmal cells, some of which have characteristic pear-shaped appearance with eccentric nucleus.

porting structure appears and is later absorbed. The nuclei often remain to the last. Proliferation of the sarcolemmal cells is a common feature although not generalized. In its earliest form it is seen as a pairing of the nuclei along the course of the fiber.

Equally constant are the changes in the nerves, which appear to suffer in the same degree as the muscles. The alterations are most marked in the smaller terminal branches, particularly alongside the muscle fibers which they

contain rather more cytoplasm. Occasionally the terminal portion of the nerve fiber may degenerate into a husklike body containing practically no axon tissue (fig. 7).

The cellular distribution is diffuse but sparse (fig. 8). Many of the scattered cells appear to be derived from the nuclei of disintegrating nerve and muscle fibers, some of them undergoing transformation into fibroblasts. Small aggregations of lymphocytes occasionally occur but are few in number, and one may examine

Fig. 7 (Mulvany). Thyrotoxic ophthalmoplegia. External-rectus muscle showing loss of striation, granulation of sarcoplasm, and reduplication of sarcolemmal nuclei. Note degenerated nerve husk (n.f.), pseudogiant cells due to portions of muscle fiber breaking off (p.g.c.), and few fat cells (f.c.). One muscle fiber is about twice the size of another.

Fig. 8 (Mulvany). Thyrotoxic eye muscle. Note scattered yet sparse cellular distribution. Many cells are derived from degenerating nerve and muscle fibers. Note nerve husk (n.f.) and pear-shaped neurilemmal cells adjacent.

many fields without encountering them. Fat cells tend to increase in number, and many of the muscle fibers show varying degrees of fatty degeneration. In severely toxic cases, the interstitial fatty infiltration may attain the proportions of a lipomatosis which occasionally may equal in degree the diffuse infiltration accompanying motor atrophy of the tongue (fig. 9).

The other orbital structures escape disturbance. The optic nerve remains healthy and there is no change in the lacrimal gland. It

appearance of exophthalmos depends on the simultaneous occurrence of weakness of the voluntary extraocular muscles and spasm of the anterior orbital smooth muscle, and it is not surprising to find that many of the associated features are based on these two factors. Others depend on complex disturbances of local muscle control, on local vascular alterations, and on

Fig. 9 (Mulvany). Thyrotoxic eye muscle showing marked fatty replacement of muscle fibers. Two lymphorrhages (lymph.) are present.

may be emphasized that edema, diffuse or extensive round-celled infiltration, or marked fibrosis is absent.

III. SYMPTOMATOLOGY OF THYROTOXIC EXOPHTHALMOS

The clinical features of this condition are so well known that observations will be confined to three items; namely, a classification of the eye phenomena grouped accordingly to mode of origin, the oculomotor palsies and their mechanism, and corneal ulceration. A few remarks on an early clinical sign will also be included.

1. CLASSIFICATION OF OCULAR PHENOMENA. It has been observed that the

exposure; while not a few, such as edema of the eyelids and ophthalmic neuralgia (both apart from corneal ulceration) and optic neuritis, are more properly features of the thyrotrophic variety of proptosis than of thyrotoxicosis and therefore have not been included in the underlying table.

a. Signs due to disturbance of orbital-muscle balance.

(1) Signs Due to Reduction of Voluntary Eye-muscle Tone

Ballet (1888): Weakness of external rectus muscle.

Basedow (1840): Lagophthalmos, inability to close eyes.

Joffroy (1893): Loss of wrinkling of forehead due to frontalis weakness.

Kast/Wilbrand (1891): Visual restriction due

to weakness of extraocular muscles.
 Moebius (1886): Difficulty in convergence.
 Suker (1917): Difficulty in following horizontal movement.

(2) Signs Due to Overaction of Orbital Smooth Musculature

Claiborne/Rogers (1920): Mydriasis in advanced cases.
 Cohen (1912): Hitch in lid movement.
 Cooper/Dalrymple (1849): Spasm of "levator palpebrae" causing upper-lid retraction and exposing sclera above iris.
 Curschmann (1922), Loewi (1921): Mydriasis following adrenalin administration.
 Gifford (1906): Difficulty in eversion of upper lid.
 von Graefe (1857): Exposure of sclera on downward movement of eye.
 Knies (1895): Dilated and unequal pupils.
 Kocher (1911): (a) Spasmodic retraction of upper lid on fixing an object. (b) On elevation, sclera is uncovered by lid moving first.
 Koller (1903), Stellwag (1869): Retraction of both lids exposing sclera above and below cornea.
 Pochin (1939b): Reduced amplitude of blinking.
 Stellwag (1869): Infrequency of blinking.

(3) Signs Due to Obscure Disturbance of Local Muscle Control

Curschmann (1917): Reversed Argyll Robertson pupil.
 Freund (1891), Knies (1895): Tremor of eyeballs; nystagmus. Hitschmann (1894), Plummer/Ryneerson (1932): Increased frequency of blinking.
 Liebrecht (1890), Hömen (1892), Rosenbach* (1919): Tremor in upper lid when closed.
 Wilder (1920): Jerking of eyes on changing from full abduction to adduction.

b. Signs due to local vascular alterations

Becker (1873): Abnormal pulsation of retinal arteries.
 Drummond (1887), Mackenzie (1890), Jellinek* (1904): Pigmentation of lids.
 Oppenheim (1887): Pigmentation of conjunctiva.
 Snellen/Donders (1871), Riesman* (1916): Bruit over eyeball.

c. Signs due to exophthalmos

Basedow (1840): Lacrimation; conjunctivitis; chemosis, especially in exposed portions of conjunctiva; keratitis; perforation leading to panophthalmitis.
 Berger (1902): Epiphora.
 Knies (1895): Corneal insensibility.

Pain/Trousseau (1868), Burrows (1925): Dislocation of both globes.

Posey/Spiller (1906): Obliteration of superior orbito-palpebral sulcus.

Sattler (1909), Vigouroux (1887): Puffiness of lids not due to edema.

Topolanski (1936): Congestion of anterior region of eye.

Many of these signs refer to one feature or a variant of it and the majority are present only in association with an obvious exophthalmos. With the exception of upper-lid retraction, very few of them are early or helpful in estimating the presence of an incipient proptosis; and the value of upper-lid retraction is not great, as its occurrence is not confined to thyrotoxicosis, being not uncommon in normal individuals, particularly when of nervous temperament, in the anxiety states, in certain lesions of the C.N.S., and in local affections of the orbit. It would be helpful, therefore, if a more accurate method of assessing an early proptosis in thyrotoxicosis were available, and it seems that this is feasible. Most observers at one time or another will have received the impression of a slight degree of exophthalmos in a particular patient in the absence of definite criteria to that effect. In some instances, retraction of the upper lid or a staring expression has created the effect; but in others it probably has been the exposure of a small rim of sclera between the iris and the lower lid. Exposure of the sclera in this position was noted early by Basedow and Stellwag; but the cases in question were advanced, and it is not generally known that careful examination will show the presence of this feature very early in the course of the disease, as soon, if not sooner, than the Dalrymple sign.

In about 90 percent of normal people it is a fact that when the head is held naturally erect and the eyes are directed horizontally forward the lower lid just meets

* The signs to which the names of Rosenbach, Jellinek, and Riesman are commonly attached were described so much earlier by other observers that the retention of these names for descriptive purposes is hardly warranted.

the lower margin of the iris, no sclera being visible between them. In thyrotoxicosis, this relationship is disturbed almost at once, owing to the combined effect of proptosis and lower-lid retraction (fig. 10). Exophthalmos by itself will produce this phenomenon very early, as was pointed out by Pochin (1938), but in exophthalmic goiter it is probable that its appearance is facilitated by a slight degree of lower-lid retraction which, however, is never marked owing to early rais-

head be held correctly. In general, this will be obtained by ensuring that a line drawn from the roof of the auditory meatus to the lower orbital margin is horizontal, but in practice visual appraisalment will suffice. A slight degree of forward tilt of the head or upward movement of the eyes will create a false white line while the reverse movements will tend to mask its presence in thyrotoxicosis. How necessary the correct stance is may be gauged from the frequency with which von

Figs. 10 and 11 (Mulvany). Early case of thyrotoxicosis. Fig. 10, showing appearance of lower scleral rim. Fig. 11, showing masking of lower scleral-rim phenomenon by raising of the level of the palpebral fissure occasioned by retraction of upper lid.

ing of the level of the palpebral fissure by retraction of the upper lid. The importance of this sign lies in the fact that it is clinically demonstrable before the exophthalmos is measurable and that it is present in about 75 percent of early cases; indeed, in the younger type of patient with the diffusely hyperplastic gland, it is almost universally perceptible and can be of particular aid to diagnosis in deciding between an anxiety state and early thyrotoxicosis when estimation of the basal metabolism may not be available and other features are equivocal. As mentioned above, however, the sign may be obscured at an early stage by the raising of the level of the palpebral fissure, which causes the lower lid once more to approximate to the margin of the iris (fig. 11). As the proptosis progresses, the white line reappears.

In examining for the test, it is important to bear in mind two points: (1) The test is delicate and it is essential that the

Graefe's sign is illustrated with the head in a position of backward tilt and the eyes directed downward. Under these conditions, normal people may show von Graefe's sign. (2) A small percentage of persons, between 8 percent and 10 percent, normally show a lower scleral rim when the conditions of the test are properly observed. In certain instances this is familial; in others it may be due to orbital shallowness, to a slight increase of orbital fat, or to some peculiarity in the conformation of the lower lid; while in a number of middle-aged men a very slight degree of unilateral and less commonly bilateral proptosis will tend to appear spontaneously. In a doubtful case, therefore, its significance should be assessed in relation to the position of the upper lid, which normally lies somewhere near the midpoint between the pupil and the top of the iris. In thyrotoxicosis, when exophthalmos is present, the upper lid is retracted;

hence the combination of lower scleral rim and upper-lid retraction is highly significant.

2. THYROTOXIC OCULOMOTOR PALSIES.

An indication of the process responsible for the appearance of the ocular palsies will have been gauged from the preliminary remarks on the mechanism of the exophthalmos in relation to thyrotoxic myasthenia and hypotonia. From the slight or moderate degree of weakness of the voluntary eye muscles which is a constant accompaniment of thyrotoxic exophthalmos to a palsy in one or other of them is a step of no great difficulty to follow, depending, no doubt, on an irregular distribution of the muscle weakness.

The thyrotoxic ophthalmoplegias bear many features in common with the eye palsies of myasthenia gravis, the points of greatest resemblance being the distribution—which may be limited to one or two muscles or more widespread, being associated with palsies of the other motor cranial nerves—and the tendency to improvement after rest or following an injection of prostigmine. Points of contrast are found in the early progression of an affected eye muscle to complete paralysis and the less characteristic response to prostigmine, a distinction probably connected with the associated neuromuscular degeneration. Nevertheless, brilliant exceptions occur. Fraser (1937) records a good response to prostigmine in a patient with bilateral ophthalmoplegia involving several muscles of about 12 years' standing, and Zondek (1938) describes a case of complete immobility of the eyeballs and generalized weakness in which most of the eye movements were restored after a single injection of 0.5 mg. of the drug (fig. 12). Improvement of this type, however, is rare and together with the myasthenic reaction is more likely to be found in the severe and rapidly progressing case.

As a rule, the thyrotoxic ophthalmoplegia is ushered in by ptosis or a diplopia, the latter being of a more stable character than that accompanying myasthenia gravis. The process may be limited to one muscle, in which case the levator palpebrae or, as noted respectively, by Moebius and Ballet, the internal and external recti.

Fig. 12 (Mulvany). Thyrotoxic ophthalmoplegia. Complete loss of ocular movement restored by prostigmine. Generalized myasthenia was also present (Zondek, 1938).

In the case of multiple lesions, bilateral ptosis with loss of lateral or vertical rotation is common, but numerous combinations are achieved although seldom without weakness in most of the other eye muscles. Total ophthalmoplegia may occur without a preliminary strabismus but is often associated with a disturbance of the cranial motor nerves and some degree of generalized myasthenia. Its course tends to be rapid, so that thyroidectomy should not be delayed.

In assessing the relative frequency of the various ocular palsies, not a great deal of help is derived from the literature, owing to the inclusion of instances of loss of eye movement accompanying the thyrotrophic type of exophthalmos. In this variety, the restriction of ocular movement is partly mechanical and occurs quite independently of any associated hyperthyroidism. It is almost exclusively in the direction of elevation in the initial

phase. Hence the impression has been gathered that paralysis of the superior-rectus muscle is the most frequent lesion in a thyrotoxic ophthalmoplegia when it is actually one of the less common. Loss of eye movement in thyrotrophic exophthalmos, however, not infrequently proceeds to total immobility, but the myasthenic reaction is never present nor is there the slightest response to prostigmine, which, indeed, is quite precluded by the

autopsy in one patient confirmed the operation findings.

3. CORNEAL ULCERATION. A few remarks concerning this complication may be of interest on account of the difference of opinion regarding the advisability of lid suture as part of the local treatment. The controversy is old and as long ago as 1896 formed the subject of discussion at a meeting of the Ophthalmological Society when no definite conclusions were attained. The origin of the disagreement appears to have been derived from a failure to distinguish between the ulceration occurring in Graves's disease and that of thyrotrophic exophthalmos. The causative factors leading to ulceration in these two varieties are different and require special methods of treatment. Corneal ulceration in thyrotoxicosis has never been common and today is still less frequent, owing to early diagnosis and treatment. When present it is generally of a superficial character which may persist with intervals of healing for many years in the absence of treatment to the thyroid gland. Little inconvenience may be caused in these cases unless secondary infection supervenes, when the condition may proceed to a panophthalmitis as it did in one of Basedow's cases. Spontaneous healing, however, without thyroidectomy is possible even in the most severe type (fig. 13). Usually the ulceration develops slowly but in certain severely toxic instances may appear rapidly and go on to perforation comparatively early.

The course and treatment of this complication differs little from that of ulceration due to more common causes. Thyroidectomy constitutes the first essential but may be combined with lid suture if the circumstances warrant it. This latter measure may be employed for all degrees of thyrotoxic ulceration when nonin-

Fig. 13 (Mulvany). End result of infected corneal ulceration following spontaneous subsidence of disease without thyroidectomy (Jes-sop, 1896).

nature of the pathologic process in the eye muscles. At this stage the differential diagnosis is straightforward, and it is of practical importance to the patient that this circumstance be recognized, for the success of Naffziger's orbital decompression in thyrotrophic exophthalmos has led to the operation's being performed needlessly in thyrotoxic ophthalmoplegia. The writer is aware that this procedure was carried out in 1938 on two patients suffering from advanced proptosis due to thyrotoxicosis—with a fatal issue in both, one succumbing from thyroid crisis and the other from auricular fibrillation. At operation, nothing was found in the orbits to account for the exophthalmos and

fect, for the tension between the lids and the globe is not severe and palpebral spasm can be relieved by section of the tissue containing the unstriated muscle at its point of attachment to the tarsal plates. The onset of infection and chemosis renders the problem more serious, owing to increasing surface tension. Relief of the pressure becomes necessary and may be accomplished by free tarsorrhaphy, by excision of portions of the chemosed conjunctiva, and by a paracentesis if complicated by hypopyon and a rising intraocular pressure. Approximation of the lids should be effected on a broad contact, aided if necessary by intermarginal splitting, as suggested by Priestley Smith (1913), but a small gap should be left at each canthus for drainage. In this way relief from pressure and exposure together with rest may be successful. Less thorough methods may be unsuccessful even when supplemented by thyroidectomy, and instances of failure have been recorded, one or both eyes having been lost before the beneficial effect of the thyroid operation could be appreciated. It is of interest to recall in this connection that after enucleation of the globe the orbital muscles were found to be atrophied and no excess of exuberant tissue was seen, a finding previously emphasized as being the constant accompaniment of thyrotoxicosis.

In thyrotrophic exophthalmos, the problem is gravely altered by the fact that the proptosis is produced by an irresistible increase of the intraorbital pressure which is countered by an equally forceful opposition from the edematous lids. The tension between the lids and the surface of the cornea may be enormous and quickly leads to chemosis and perforation. It follows therefore that lid suture here, however cleverly aided by tarsorrhaphy, will serve only to aggravate the vicious char-

acter of the morbid process. Hence disaster is the common sequel to treatment of this type of ulceration by lid suture, and it should be recognized that the sole means of saving the eye at this stage, as advocated by Naffziger, lies in orbital decompression.

4. TREATMENT OF THYROTOXIC EXOPHTHALMOS. Apart from local measures directed to effects resulting from exposure, treatment obviously will be directed to relief of the general condition, although regression of the proptosis following may be slight or even absent. The reason for this anomaly is fourfold: first, the stretching of the degenerated voluntary muscles has led to permanent lengthening of their fibers; second, retraction of the tissues lying between the lids and the region of the equator of the eye has occurred and tends to persist; third, the extensive morbid process involving the neuromuscular mechanism impedes the early return of normal tone and consequent ability of the muscle to retract; and lastly, with the fall in the basal metabolism, the retrobulbar space fills up with a more solid type of fat. The best chance of improving the exophthalmos after operation consists in aiding the retraction of the extraocular muscles during the early period of restoration of tone. This may be obtained by pressure on the globes sustained during sleep and for as many hours during the day as possible. After a few weeks the measure may be discontinued as the maximum improvement will then have taken place.

In cases of severe and persistent exophthalmos, the effect can be minimized by a narrowing of the palpebral fissure. This can be achieved by a tarsorrhaphy uniting the lids in the outer fourth or fifth of their extent. The maneuver has the merit of simplicity and is capable of re-

versibility should this be desirable. An alternate measure, particularly when lid retraction is marked, consists of a plastic operation of the type devised by Goldstein (1934), which has the effect of veiling the proptosis without producing a ptosis. A similar result has been obtained by a cervical sympathectomy, but the outcome of the operation is uncertain and disappointing. It is advisable, therefore, first to assess its possible value by ex-

amining the effects of local anesthesia of the lower cervical ganglion. Undoubtedly, the first measure is the one of choice. Concerning the treatment of the ocular palsies, when improvement has failed to follow a thyroidectomy, this should consist of the usual methods of advancement and recession of the affected tendons after an appropriate interval to allow of recovery of muscle tone has passed.

(Part II will appear in the next issue.)

SUGAR CONTENT OF CATARACTOUS HUMAN LENSES*

PETER W. SALIT, PH.D.

Iowa City, Iowa

Investigators have been interested in the sugar content of the crystalline lens for a long time—that is, since 1854, according to Lottrup-Andersen¹—but their investigations were of only qualitative nature up to 1927, when Lottrup-Andersen for the first time made quantitative determinations. This author discusses some 33 references, only half of which reported sugar in the crystalline lens; all others failed to detect any sugar whatsoever. Lottrup-Andersen, using the modern Bang-Hagedorn micro-method, not only proved with certainty the presence of sugar in both normal and cataractous human lenses, but also showed wide variations in the sugar content between individual lenses of the same type as well as between groups of different kinds of lenses—that is, cataracts of the more common type, diabetic cataracts, and normal lenses. Their average sugar values were 46.3, 82.0, and 60.0 mg. percent, respectively. The analyses, however, were carried out on a rather small number of lenses—that is, 22, 3, and 5 lenses, respectively—and no attempt was made to

make comparisons between incipient, intumescent, and mature cataracts, on the one hand, and the different stages of sclerosis on the other as well as to compare the results on the basis of age. The average age of patients from whom normal lenses were obtained was considerably lower than that of the cataract patients, and this difference in age may have had something to do with the stated difference between the respective sugar values.

The present study was undertaken to supplement Lottrup-Andersen's work along the suggested lines.

The sugar was determined by a modification of Gibson's² colorimetric method for finger-tip blood sugar. Since by this modified procedure very small quantities of sugar can be accurately and rapidly estimated in any kind of solid animal tissue that gives clear supernatant fluid after the precipitation of the protein, it is given here in detail.

All the reagents were prepared as described in Gibson's method. After the lens was weighed on a small piece of filter paper, it was transferred, together with the filter paper, to a thick-walled 15-c.c. centrifuge tube. To this were added 3 c.c.

* From the Department of Ophthalmology, College of Medicine, State University of Iowa.

of a freshly prepared mixture of the 1.25-percent sodium tungstate solution and the two-thirds N sulfuric acid in the proportion of 7 to 1, this proportion being more effective in precipitating the lens protein than Gibson's 5 to 1. The lens was removed from the filter paper into the tip of the tube by means of a blunt glass stirring rod and macerated and dispersed as finely as possible. Then the filter paper was treated in the same way and intermixed with the lens particles. The tube was stoppered and centrifuged at the rate of

$$\frac{15 \times 0.08 \times 100}{S \times W \times 0.667} = \text{mg. percent sugar,}$$
or
$$\frac{15 \times 0.08}{S \times 0.667} = \text{mg. sugar per lens.}$$
In these formulas, 15 = the color reading of the standard, 0.08 = mg. sugar in 2 c.c. of standard, S = the color reading of the sample, W = weight of sample in grams, and 0.667 = two thirds of sample.

In all, 191 senile cataractous lenses, extracted by the intracapsular method, were analyzed. The results are arranged according to stage of cataract (table 1),

TABLE 1

MINIMUM, MAXIMUM, AND AVERAGE SUGAR VALUES OF CATARACTOUS LENSES ACCORDING TO STAGE OF DEVELOPMENT

Stage of Cataract	No. of Lenses	Age of Patient	Duration years	Weight gm.	Mg. per Lens	Mg. % in Lens	Mg. % in Blood
Incipient	118	40-87	0.5-20.0	0.1180-0.3055	0.022-0.176	10.4-58.0	44-297
Average		70.7	2.3	0.2061	0.085 (0.084)*	40.1 (39.5)*	131 (130)*
Intumescent	32	43-84	0.5-10.0	0.1256-0.2775	0.034-0.310	23.4-95.2	51-200
Average		70.1	2.8	0.2089	0.096 (0.076)*	47.1 (42.2)*	138 (121)*
Mature	41	51-86	0.7-12.0	0.1236-0.2300	0.033-0.191	18.4-84.3	72-221
Average		72.2	2.9	0.1807	0.073 (0.065)*	37.1 (35.1)*	130 (127)*

* Diabetics excluded: Incip. 1 diab., 0.85 percent; Intum. 4 diab., 12.5 percent; Mat. 1 diab., 2.4 percent.

3,500 r.p.m. for approximately 10 minutes. The supernatant fluid was decanted into a 15-c.c. centrifuge tube, and 2 c.c. were used (in a Folin-Wu sugar tube) for analysis. In another tube 2 c.c. of the 0.004-percent sugar solution were used as standard. To each tube were added 2 c.c. of the alkaline copper tartrate reagent, and the contents were well mixed. The tubes were heated for six minutes in boiling water. After cooling under tap, 2 c.c. of the arseno-phosphotungstic acid reagent were added to each tube, and the contents were well mixed. Both sample and standard were diluted to 10 c.c. and mixed by inverting the tubes several times, after which their colors were compared in the colorimeter. For calculation the following formulas were used:

stage of sclerosis (table 2), and age of the patient (table 3).

The average duration of failing vision varies from 2.3 years for incipient cataracts to 2.8 years for intumescent and 3.9 years for mature cataracts.

The average weight of the lens increases from 0.2061 gm. in incipient cataracts to 0.2089 gm. in intumescent cataracts, then decreases to 0.1807 gm. in mature cataracts.

The 191 cataracts included six lenses from diabetics, one of which was incipient, four intumescent, and one mature. In terms of percentage they constitute 0.85, 12.5, and 2.4 percent of the total numbers (118, 32, 41) of the three groups of lenses, respectively. The sugar values in parentheses (see tables), marked with an

asterisk, represent averages exclusive of diabetics.

The absolute sugar values, or milligrams per lens, including diabetics, are 0.085, 0.096, 0.073 mg. for incipient, intumescent, and mature cataracts, respectively; with diabetics excluded, they are 0.084, 0.076, and 0.065 mg. In terms of milligrams percent, they are 40.1, 47.1, 37.1, and 39.5, 42.2, and 35.1, respectively. Thus in terms of milligrams percent there is a considerable increase in the sugar content in intumescent and some decrease

the lens only simultaneously. On the other hand, the fact that 12.5 percent of the intumescent cataracts come from diabetics (as against 0.85 and 2.4 percent for incipient and mature cataracts), shows a rather intimate connection between intumescence and diabetes, and it is reasonable to assume that diabetes may have something to do with the causation of intumescence and not vice versa. This assumption is strongly supported by the fact that the average sugar value (42.2 mg. percent) of intumescent cataract, exclu-

TABLE 2

MINIMUM, MAXIMUM, AND AVERAGE SUGAR VALUES OF SCLEROSED LENSES ACCORDING TO STAGE OF DEVELOPMENT
